Figure 7 Recurrent disk herniation. Persistent pain after back surgery may be due to postoperative scar or recurrent disk herniation. These two entities are radiographically indistinguishable without the benefit of contrast enhancement. The distinction is crucial in that surgery can be successful in alleviating pain in patients with a recurrent disk herniation, while surgery is not recommended in the presence of scar alone. The patient had persistent low back pain radiating to the right lower extremity following surgery for a herniated disk. (a) The precontrast T_1 -weighted axial image at the L5–S1 intervertebral disk level reveals a right paracentral mass displacing the dural sac posteriorly and medially. (b) Following contrast administration, enhancement is limited to the rim of the mass, making possible the diagnosis of a recurrent disk herniation. Postoperative scar would have demonstrated uniform enhancement

Figure 8 Diskitis. MRI is the modality of choice in the diagnosis of diskitis. Degenerative changes of the spine may have a similar appearance to infection on noncontrast examination. This patient had recent back surgery and complained of increasing pain. (a) The precontrast T_1 -weighted sagittal examination reveals decreased signal intensity of the vertebral body endplates adjacent to the intervertebral disk at one level. (b) Following contrast administration, both the disk and endplates enhance. Enhancement also improves recognition of abnormal paravertebral soft tissue. Both findings point to the diagnosis of infection

Although most neoplastic disease, regardless of its location (intramedullary, intradural, or extradural), demonstrates enhancement following gadolinium chelate administration, it is particularly in the intradural compartment that contrast finds its greatest application.¹² Differentiation between neoplastic and non-neoplastic syrinxes is markedly improved.¹³ In addition, the sensitivity to small intradural extramedullary tumors, in particular leptomeningeal disease, is greatly increased.¹⁴

4 CLINICAL APPLICATIONS IN THE BODY

Abnormal accumulation of gadolinium chelates following intravenous administration can be demonstrated on MRI in early myocardial infarction. This finding has been used to improve the depiction of acute and subacute infarction.¹⁵ However, initial results with gadolinium chelates were disappointing in the liver. At a dose of 0.1 mmol kg^{-1} with conventional 5–10 min duration scans, many lesions became isointense following contrast administration, thus decreasing their detectability. This situation has been reversed by the implementation of dynamic imaging and bolus contrast

administration.¹⁶ Imaging with this approach provides both improved lesion detectability and lesion characterization (Figure 9). The clinical introduction of gadolinium chelates to assess both renal and hepatobiliary excretion provides an additional dimension to postcontrast liver examinations. The first agent in this class to receive clinical approval was gadobenate dimeglumine. With such an agent, dynamic postcontrast scans are initially acquired. These are, in essence, identical to that using an agent with pure extracellular distribution. Delayed scans, reflecting the hepatobiliary uptake of the agent, are obtained 1–2 h following injection. Delayed scans can be used to advantage for improved detection of small metastatic lesions, as well as for characterization of tissue according to the presence or absence of functioning hepatocytes.¹⁷

In general body imaging, there is excellent tissue differentiation provided by T_1 - and T_2 -weighted images without contrast administration. Despite this intrinsic tissue contrast, gadolinium chelate administration has proven valuable in specific clinical problems.¹⁸ These include the identification of recurrent tumor, differentiation between benign and malignant tumors, and identification of necrotic tissue.¹⁹ Initial studies in the abdomen, pelvis, and extremities have focused on improved tumor detection and differential diagnosis.

Figure 9 Metastatic liver disease from colon cancer. (a) T_2 -weighted fast spin echo scan. Breathhold T_1 -weighted gradient echo scans prior to (b), 1 min after (c) and 80 min after (d) intravenous injection of gadobenate dimeglumine (Gd BOPTA). This chelate has both renal and hepatobiliary excretion. Initial postcontrast scans depict the extracellular distribution of the agent, with delayed scans reflecting hepatobiliary uptake. The precontrast T_2 -weighted scan is normal, with the precontrast T_1 -weighted scan raising the question of several lesions. At least four metastatic lesions (arrows) are well seen on both the dynamic (c) and delayed (d) postcontrast scans. The signal intensity difference between the lesions and normal surrounding liver, and thus lesion conspicuity, is markedly improved postcontrast. Both dynamic and delayed scans are typically acquired following injection of gadobenate dimeglumine, with dynamic scans useful for lesion detection and characterization and delayed scans important for improved detection of small lesions. 5 FUTURE DIRECTIONS

In recent years, several new chelates have been introduced in competition to the single agent initially available, gadopentate dimeglumine, which defined this class of contrast media. Clinical use now includes four compounds, gadopentate dimeglumine [$\text{NMG}_2(\text{Gd DTPA})$], gadoterate meglumine [$\text{NMG}(\text{Gd DOTA})$], gadodiamide (Gd DTPA-BMA), and gadoteridol (Gd HP-DO3A). At the same dose, these agents show little difference with regard to enhancement characteristics.

However, they can be differentiated on the basis of stability, osmolality, and viscosity (Table 1). Future development of extracellular agents is likely to be confined to the ring-shaped chelates, which demonstrate greater in vitro and in vivo stability.

Initial clinical trials with gadopentate dimeglumine were principally confined to a single dose (0.1 mmol kg^{-1}), due to concerns about safety at higher doses. With the introduction of gadoteridol, a more kinetically inert agent, and continued experience with other compounds, interest has been renewed in the subject of contrast dose. This interest has led to several clinical trials with high dose, using $0.2\text{--}0.3 \text{ mmol kg}^{-1}$. As noted in the section on head applications, it has been shown that higher doses, and in particular 0.3 mmol kg^{-1} , provide improved detectability of brain metastases. Preliminary work in brain infarction and infection suggest broader clinical applicability for high doses.

Although work to date has focused on gadolinium chelates with extracellular distribution and renal excretion, it is also possible to synthesize agents with some tissue selectivity. How far this work will go is unknown, although promising initial results have been obtained with agents (such as gadobenate dimeglumine) which demonstrate partial hepatobiliary excretion.²⁰ Chemical synthetic work is also in progress in an attempt to increase the relaxivity of compounds per gadolinium ion, opening possible other doors relative to clinical applications.

6 CONCLUSIONS

As with MRI itself, the clinical importance of contrast media has far exceeded initial expectations. Gadolinium chelates today play a dominant role in clinical MRI, with applications which encompass nearly every major examination type. Improved lesion identification, differential diagnosis, and definition of lesion extent are direct results of this development.

1 INTRODUCTION

Since the relaxation times of the nuclei of interest—the hydrogen protons of the water molecules—determine the MRI signal intensity exponentially, even a slight modification of the relaxation times exhibits a significant change in the signal strength. Substances characterized by at least one unpaired electron are known to enhance the relaxation process very effectively. Hydrophilic compounds from the nitroxyl class were found to be interesting candidates because of their good tolerance.¹ However, the paramagnetic effect of these cyclic organic molecules is relatively weak inasmuch as it derives from just one unpaired electron. Elements from the series of transition metals offer a more realistic approach for developing substances to be used as contrast agents for MRI.

The first publications on the use of paramagnetic metals as contrast agents appeared at the beginning of the 1980s.^{2,3} In particular, manganese chloride with its five unpaired electrons was discussed as the prototype of a paramagnetic contrast-giving compound. The free ions of the transitional elements (e.g. Mn^{2+} , Cu^{2+} , Fe^{3+} , and Cr^{3+}) exert a stronger paramagnetic effect, but are unsuitable for clinical use because of their interaction (toxicity) with the body and their poor solubility at pH 7.

Due to its seven unpaired electrons, the gadolinium ion exhibits the strongest effect of all elements on T_1 relaxation times. The element gadolinium belongs to the lanthanides; the term 'rare earths' also used for these compounds is somewhat misleading because the concentration of lanthanides in the Earth's crust is about 100 times higher than that of iodine. Tons of lanthanides are used in industry as antiknock agents, in TV screens, in lasers, glasses and ceramics, to name just some applications. Use of the gadolinium ion in the form of its chloride, sulfate or acetate is prohibited by its poor tolerance by the body. Like many other metallic salts, these compounds form acid solutions in water, and insoluble hydroxides or phosphates arise in the neutral pH range which quickly accumulate in the reticuloendothelial system after intravenous administration. These compounds are therefore unable to provide optimum contrast-giving properties.

The purpose of this article is to summarize the different possibilities of using stable and biologically inert gadolinium chelates as contrast agents for diagnostic imaging. Their safety profile and their pharmacodynamics will be discussed in detail with special attention to the first and most widely used contrast agent: Magnevist®. Future developments of tissue specific

agents will expand the potential of this new class of pharmaceuticals based on the paramagnetic atom gadolinium.

2 CHEMISTRY OF GADOLINIUM-BASED CONTRAST AGENTS

The gadolinium ion is that paramagnetic species which most efficiently enhances the signal in magnetic resonance imaging. It has seven unpaired electrons distributed isotropically in its 4f shell. Since tolerance of the ion in laboratory animals is not sufficient to allow clinical studies, it was necessary to detoxify the gadolinium ion without eliminating the paramagnetic effect or, to be more precise, without affecting the enhancing properties too much. This goal was achieved by chelation of the ion with various ligands. The basis for the chelation of metal ions by coordination with suitable ligands is described in several excellent monographs and reviews.^{4,5}

The effective chelation of an ion affords an array of atoms that are capable of interacting with the ion. Chelation can be achieved by electron donation of an electronegative atom to the ion. This process can be regarded as the interaction of an acid with a base. The metal ion functions as the acid and the donating atom as the base. The force of interaction can be described by the principle of hard and soft acids and bases.⁶ Pearson⁷ came up with this concept by which reactivities and stabilities may be predicted. Chemical entities including atoms, ions and radicals are classified as 'hard' and 'soft' Lewis acids or bases. The 'hard' species have a small atomic radius, high charge and low polarizability, whereas 'soft' species possess the opposite characteristics. The principle states that acids show greater affinity for bases of the same class, and vice versa. Thus, hard acids (acceptors) tend to form strong bonds with hard bases (donors), but bind reluctantly or weakly to soft bases.

With respect to the principle, Gd^{3+} is regarded as a hard acid. Hard bases are neutral or negatively charged oxygen species, nitrogen is also regarded as a hard base, but to a lesser extent than oxygen. On the other hand, sulfur and phosphorus are soft bases. According to this classification the gadolinium ion is most effectively coordinated by oxygen and nitrogen, and all gadolinium chelates which are used clinically take advantage of this relationship. The backbone of most chelation agents is derived from polyazapolycarboxylic acids. As can be seen from Figure 1 both open chain and macrocyclic gadolinium chelates are used.

Although the nature of the coordinating atoms (oxygen and nitrogen) are the same, there are differences concerning the stability of the chelates. One has to look at both the thermodynamic and the kinetic stabilities, as these potentially influence the pharmacology of the agents (see Table 1). Since macrocyclic chelates exhibit high kinetic stabilities⁸ they are not likely to undergo transchelation with metals that occur in vivo. On the other hand, the open chain chelates can equilibrate rapidly with endogenous metals.⁹

The characteristic coordination number of Gd^{3+} is, in many cases, 9. Gadolinium has neither the restricted coordination number nor the restricted geometry of transition metal complexes which are imposed on the latter by the requirement for orbital overlap in bonding. In aqueous solution Gd^{3+} is coordinated by nine water (and/or hydroxyl groups) molecules. In the chelates shown in Figure 1 the ligands deliver eight co-

Figure 1 Chemical structure of gadolinium chelates used as contrast agents in MRI

ordination sites (oxygen and nitrogen atoms); the ninth position is occupied by a water molecule and it is this water molecule in the first coordination sphere of the ion that contributes most to the signal enhancing properties of the chelate. X-ray crystallographic structure determinations have been performed on all four chelates mentioned. The coordination geometries of all these chelates are remarkably similar and the typical structure is best described as a distorted tricapped trigonal prism.¹⁰

Gadolinium chelates are formed by the direct reaction between stoichiometric amounts of a polyazapolycarboxylic acid and gadolinium oxide. The synthesis of the clinical compounds is well described. The starting material for gadopentetate dimeglumine¹¹ and gadodiamide¹² is pentetic acid [diethylenetriaminepentaacetic acid, (DTPA)]. The macrocyclic products gadoterate meglumine¹¹ and gadoteridol¹³ are synthesized starting with 1,4,7,10-tetraazacyclododecane.

Chelation of the metal ions leads to a dramatic change in their pharmacological and toxicological properties.¹⁴ One of the most important alterations is the dramatic improvement in their solubility in water at neutral pH. Gd-DTPA and other comparable metal chelates are extremely hydrophilic substances with a partition coefficient between butanol and water of sometimes less than 0.001. The positive charge of the central paramagnetic metal ion such as Gd³⁺ is compensated by the negative charge of the ligand. If necessary, any excess negative charge of the ligand can be compensated by counter cations such as (meglumine)⁺ or Na⁺. A highly concentrated and stable aqueous solution (0.5 mol L⁻¹) is a special prerequisite for a diagnostic agent administered intravenously in small volumes.

The ligand can modulate the paramagnetic properties of the free metal ion. Lauffer has described this subject in greater detail in a recently published review.¹⁵ A closer examination of the multifactorial term, the correlation time τ_c , which describes the interaction between the paramagnetic ion and the atomic nucleus that is to be affected, reveals that relaxivity can be optimized depending on field strength. At a field strength of 1 T the optimum values are obtained with a correlation time of approximately 10⁻⁸ s. The correlation time τ_c is made up of at least three variable factors:

$$\tau_c^{-1} = \tau_s^{-1} + \tau_m^{-1} + \tau_r^{-1} \quad (1)$$

where τ_s is the longitudinal electronic relaxation time of the paramagnetic ion, τ_m is the lifetime of the proton in the complex, and τ_r represents the rotational relaxation time due to Brownian rotational motion.

The rotational correlation time τ_r of low molecular weight compounds is so short that it is usually the determining factor for the overall correlation time. Taking 1 T, for example, a correlation time of approximately 10⁻⁸ s would be desirable in order to achieve optimum relaxivity. For low molecular weight gadolinium complexes such as Gd-DTPA, τ_r is in the order of 10⁻¹⁰ s and thus too short to elicit perfect relaxation. Consequently, a longer rotational correlation time has to be attained by raising the viscosity of the medium or by increasing the size of the paramagnetic molecule. Using larger molecules the rotation rates decline to such an extent that they are no longer the determining factor in the correlation time τ_c . High molecular weight gadolinium chelates exhibit an improvement in the T_1 relaxivity which levels off at about 15 L mmol⁻¹ s⁻¹. In these compounds it is the electronic relaxation time and the intramolecular motion that determine the influence on the relaxation time of the nuclei to be affected.

In addition to the optimization of τ_c , there is another way in which relaxivity can be increased. Relaxivity is determined more or less linearly by the number of water molecules that interact directly with the paramagnetic ion. In the case of gadolinium there are, in principle, nine available coordination sites where water binding can take place. Depending on the pH value of the aqueous solution, some of those coordination sites may be occupied by anions (e.g. Cl⁻ or OH⁻) or water molecules. The complexation of the gadolinium ion diminishes its interaction with OH⁻ and the pH dependency of the relaxivity. The ligand occupies several coordination sites of the metal ion. However, even in the least favorable case [gadolinium triethylenetetraminehexaacetic acid (GdTTTHA)], when all the coordination sites are occupied, the central ion can decrease the relaxation times of the bulk water molecules, and a T_1 relaxivity of about 2 L mmol⁻¹ s⁻¹ at 0.47 T was measured. This may correspond to outer sphere relaxation. If too many coordination sites are unoccupied, the possibilities for unwanted interaction (transchelation) between the central atom and endogenous substances of the organism increase.

The goal is to find compounds with correlation times of about 10⁻⁸ s. Such substances, probably of oligomeric or polymeric nature, could elicit relaxivities of up to 50 L mmol⁻¹ s⁻¹ per metal ion. Certain chelates (polymeric substances) are very useful for enhancing the paramagnetic effect. In this particular situation the strength of the magnetic field is of special

Table 1 Thermodynamic Stability Constants for Clinically used Gadolinium Chelates

Chelate	log(K_{Therm})
Gadopentetate dimeglumine	22.5
Gadodiamide	16.9
Gadoterate meglumine	24.7
Gadoteridol	23.8

importance. Polymeric chelates display their optimum relaxivities in the range between about 0.5 and 1.0 T.

3 TOLERANCE AND PHARMACOLOGY OF GADOLINIUM CHELATES

The major concern about the use of metal chelates was the potential release of the metal ion from the chelate. PbEDTA which was investigated as a potential contrast agent for X-ray studies in man in the mid-1950s was not useful because of severe side-effects, probably due to intoxication by the released toxic metal ion.

All transition metals exhibit intolerable toxicity. However, gadolinium does not belong to the class of metals such as cadmium or lead with high toxicity. After intravenous administration in the rat, the gadolinium salt displayed an LD₅₀ of about 0.5 mmol kg⁻¹. The tolerance of the chelator DTPA was even lower. The chelation of the lanthanide drastically changes not only its water solubility but also the tolerance profile and pharmacological behavior. Most of the basic pharmacological properties were investigated when the dimeglumine salt of the gadolinium complex of DTPA (generic name gadopentetate dimeglumine, for short Gd-DTPA) was commercially developed as the first contrast agent for MRI in the early 1980s.¹⁴

It has been shown in animal experiments that toxic effects of Gd-DTPA occur only at very high dosages. For instance, an intravenous LD₅₀ in the range of 10 mmol kg⁻¹ was found for rats, mice, rabbits and dogs. The gadolinium complex is also highly stable under physiological conditions. The ions occurring in plasma do not displace the gadolinium atom from its complex bond. Autoradiographic trials and tissue distribution studies with the ¹⁵³Gd and double-labeled (¹⁵³Gd/¹⁴C) compound demonstrate the excellent in vivo stability of the substance. Excretion and tissue distribution studies revealed complete elimination with no body retention of the agent.

In subchronic toxicity studies in rats and dogs the compound was administered over a period of 4 weeks in a daily dose of up to 5 mmol kg⁻¹. Vacuolization of the proximal tubuli (osmotic nephrosis) was the most obvious sign of toxicity. Cardiovascular tolerance tests in dogs proved that the compound is safe when administered intravenously. None of the toxicological tests elicited a specifically metal ion induced intolerance profile.

Magnevist[®], the aqueous formulation of Gd-DTPA containing 0.5 mol L⁻¹, was the first contrast medium approved for clinical use in cranial and spinal MRI in Germany, the USA, Japan, Switzerland and The People's Republic of China in 1988. These approvals were extended to whole body MRI with a total dose of up to 0.2 mmol kg⁻¹ bodyweight in patients older than 2 years of age. Up to 1993, more than 7 million patients have been diagnosed using Magnevist[®] contrast enhanced MRI. The pharmacokinetic properties of the compound are very much the same as those of well known radiographic contrast agents.

After intravenous injection, Gd-DTPA is distributed in the extracellular water space of the body. Gd-DTPA leaves the organism in unaltered form by renal excretion with a half-life of about 1–2 h. The extrarenal elimination is negligible. Gd-DTPA does not diffuse through plasma membranes, and is

therefore unable to pass the intact blood–brain barrier; it is thus an excellent tool for investigating accurately any disturbances of the barrier. The detection of lesions such as metastases improves after a dose of 0.1 mmol kg⁻¹ corresponding to 0.2 mL kg⁻¹ or 10–20 mL of Magnevist[®] per patient.

The first clinical trials were conducted at the end of 1983 in the Department of Radiology of the Free University of Berlin (Professor R. Felix¹⁶) and the Hammersmith Hospital, London (Professor R. Steiner).¹⁷ The tolerance of Magnevist[®] is excellent. Results from standardized protocolized European clinical trials in more than 13 000 patients demonstrate that the incidence of adverse drug reactions (ADRs) was even lower than that of non-ionic X-ray contrast agents.¹⁸ A value of 1.46% ADRs including local warmth was recorded. Almost the same value was found in a US study.¹⁹ It was shown that there are no hemodynamic alterations in patients following bolus injection of doses up to 0.3 mmol kg⁻¹.²⁰

The favorable safety profile was also confirmed by results of postmarketing surveillance reports.¹⁸ Severe adverse reactions can occur, but the incidence of life threatening reactions is very rare. Out of more than 5 million applications conducted up to December 31, 1992, 60 severe drug reactions (convulsion, edema of the glottis, anaphylactoid shock, and death) were reported. In some cases a causal relationship between the ADR and the drug injection was not clear. In patients with impaired renal function, the half-life in the plasma and the urine is delayed.²¹ However, the compound can be eliminated from the plasma by dialysis.²²

The tolerance of a biologically inert substance is determined by its physicochemical properties. Although the osmotic load produced by the intravenous injection of 0.1 mmol kg⁻¹ bodyweight of Magnevist[®] is extremely low, a much higher dosage might be necessary in special circumstances. This consideration led to the synthesis of gadolinium complexes with reduced osmotic activity (see Figure 1 and Table 2).

By converting two of the carboxyl groups of the DTPA molecule into amides, neutral gadolinium complexes (e.g. gadodiamide) with reduced osmolality (0.5 M = 0.78 osmol kg⁻¹) and improved acute intravenous tolerance (LD₅₀ in rats >25 mmol kg⁻¹) were obtained.⁹ In addition to the open chain metal complexes, macrocyclic gadolinium complexes were developed. One of the first of these compounds was gadoterate meglumine (GdDOTA, Dotarem[®], Laboratoire Guerbet, France). Dotarem[®] is a cyclic compound with four carboxyl groups and is characterized by excellent tolerance.²³ By 1993, Dotarem[®] was available in a limited number of European and South American countries. Unlike gadoterate meglumine, gadoteridol is an electrically neutral macrocycle. Gadodiamide (Omniscan[®]) and gadoteridol (ProHance[®]) were introduced on to the US market at the beginning of 1993 (marketed by Nycomed and Bracco, respectively).^{24,25}

All clinically used extracellular gadolinium chelates exhibit virtually identical contrast enhancing and pharmacological properties. It is too early to confirm significant differences in the safety profile between the new agents and Magnevist[®], although some publications highlight a somewhat higher incidence of ADRs in patients investigated with ProHance[®].²⁶ Obviously, large clinical trials are needed to explore any differences between the tolerance profile of Magnevist[®] and that of the new agents.

Table 2 Gadolinium Chelates used in Clinical Practice^a

Generic name	Trade name	Company	Year of first marketing approval	Type of chelator	Osmolality ^b (osmol kg ⁻¹)
Gadopentetate dimeglumine	Magnevist	Schering AG, Germany	1988	Open chain	1.96
Gadoterate meglumine	Dotarem	Guerbet, France	1989	Macrocylic	1.35
Gadodiamide	Omniscan	Nycomed Imaging AS, Norway	1992	Open chain	0.78
Gadoteridol	ProHance	Bracco SpA, Italy	1992	Macrocylic	0.63

^aMarketing authorization by the health authorities is different in the various countries with respect to the mentioned gadolinium complexes and their application.

^bThe values for the 0.5 M formulations are taken from the package inserts of the commercially available agents.

4 PRINCIPLES OF CONTRAST ENHANCED MRI

The mechanism of action of a paramagnetic contrast agent in MRI is very complex. Although the phenomenon of relaxation was described by Bloembergen and co-workers as early as the mid-1950s, the enhancement effect cannot simply be transferred from spectroscopy to the imaging technique. The situation in a living organism is very complicated. Physical factors like motion, temperature, viscosity, binding to biomolecules and compartmentalization influence the relaxation rates of the bulk water and the relaxivity of paramagnetic materials.

Even the phenomenon of contrast enhancement in pure water is confusing at first glance. In a classical imaging sequence such as a T_1 -weighted spin echo experiment, the signal intensity increases nonlinearly with the concentration of the contrast agent, reaches a maximum, and then decreases nonlinearly as the concentration continues to increase (Figure 2). The decrease of the intensity at higher concentrations is due to the T_2 effect of the paramagnetic substance.

The contrast effect depends to a great extent on the MRI sequence applied. Generally, the best enhancement is achieved using T_1 -weighted techniques such as a spin echo sequence with a TR of <0.6 s and a short echo delay time TE of <0.04 s. Optimal are those techniques with very short TR

and TE times. Gradient echo techniques are also useful, provided an adequate pulse angle is applied (e.g. Ernst angle). However, in clinical practice some contrast enhancement is also visible on the application of proton density or even T_2 -weighted imaging sequences, since the applied repetition rates of 1.5–2.0 s are not sufficient for full relaxation of most of the protons.

The strength of the magnetic field modulates the contrast effect in two ways. First, the relaxivity is field dependent. The relaxivity of low molecular weight substances decreases with increasing field strength, but the differences are relatively weak in the field range of diagnostic imaging units (0.04–2 T). Second, the intrinsic relaxation times of the nuclei in the organism are also field dependent. At low field strength (<0.1 T) the tissue already has very low relaxation times and a further decrease of the relaxation time does not lead to a significant increase in the signal intensity. A very good effect of the contrast agents is seen at high field strength because of the longer intrinsic relaxation times of the tissue protons.

At least three factors regulate the contrast-enhancing ability of the tissue:

1. distribution volume of the contrast material;
2. concentration and relaxivity of the contrast material;
3. intrinsic relaxation times of the tissue without the contrast material.

Only tissues with a large distribution volume of the paramagnetic contrast material and a long intrinsic relaxation time exhibit a significant change in their relaxation times. In consequence, marked contrast enhancement is visible only in those areas (lesions) with increased extracellular space or distribution volume. Contrast is seen, therefore, in lesions (inflammation, tumor, edema) or large accumulations of fluids (urine). No significant increase in intensity is seen in tissues (e.g. normal brain, liver, muscle) with small distribution volumes and/or short intrinsic relaxation times. An already short intrinsic T_2 relaxation time allows almost no increase in signal intensity using a paramagnetic contrast agent, but may respond to a T_2 -sensitive relaxation agent (e.g. ferrites) which decreases the signal intensity.

Relatively low concentrations of a paramagnetic species are needed to reduce the T_1 relaxation time significantly. A gadolinium concentration as low as $10 \mu\text{g mL}^{-1}$ is sufficient to elicit a strong effect on the signal intensity. The strong paramagnetism of gadolinium ions, even when chelated, facilitates the relaxation of nearby water protons causing both T_1 and T_2 relaxation times to decrease. Although both T_1 and T_2 times are affected, the T_1 shortening effect predominates for MRI at

Figure 2 Contrast enhancement of a hypothetical tissue using different concentrations of a homogeneously distributed paramagnetic gadolinium chelate (Gd-DTPA). The calculations using the exponential equation of a spin echo sequence taking into account the various TR , TE , T_1 , and T_2 values were performed with intrinsic T_1 and T_2 times of 0.8 and 0.2 s and relaxivity values of $R_1 = 4.5 \text{ L mmol}^{-1} \text{ s}^{-1}$ and $R_2 = 5.5 \text{ L mmol}^{-1} \text{ s}^{-1}$

low concentrations. However, at very high concentrations (>5 mmol L⁻¹, depending on the sequence parameter) the T_2 or susceptibility effect of gadolinium dominates even in T_1 -weighted imaging, and signal reduction occurs. Using current clinical doses of 0.1 mmol kg⁻¹, such a T_2 effect can only be observed in the urinary bladder. Contrast enhancement is almost undetectable in the normal brain parenchyma because the cerebral blood volume is very small (about 2–3% of total volume) and extracellular gadolinium chelates are unable to pass cellular membranes such as the intact blood–brain barrier.

In combination with its conventional T_1 -based signal enhancement properties, the T_2^* effect of gadolinium chelates is of interest in those imaging studies²⁷ where quantification of the blood supply is of clinical relevance. Ideal conditions for gadolinium complexes such as susceptibility agents can be found in the brain where only slow water diffusion due to the blood–brain barrier occurs, and the distribution volume of the contrast agent is limited. Even bolus injection of 0.1 mmol kg⁻¹ of Gd-DTPA (Magnevist®) in conjunction with T_2^* -weighted gradient echo imaging was sufficient to generate maps of cerebral blood volume in patients.²⁸ Since the T_2^* effect is directly proportional to the magnetic moment, the efficacy of gadolinium as a T_2^* agent is about 30% less than for the same complex based on dysprosium.

5 TISSUE-SPECIFIC GADOLINIUM COMPLEXES

One of the disadvantages of currently available contrast agents for MRI is their relatively unspecific distribution in the organism. The compound reaches all tissues in a more or less homogeneous concentration. Exceptions are the excretory organs, the vascular space (shortly after administration only) and certain organs such as the brain. An improvement in the diagnostic potential may be attainable by directing the paramagnetic molecule to targets of interest, thus achieving higher local concentrations, and this may allow for a reduction in the dose and should lead to an improvement in the differentiation between target and surrounding tissue.

Extracellular compounds such as Gd-DTPA are highly tissue specific with respect to their accumulation in the kidneys. When compared with other tissues, much higher concentrations are reached because of renal elimination. This effect is the basis of contrast-enhanced urography by means of heavily T_1 -weighted imaging sequences.²⁹ One of the most important tissues, the vascular system, can be targeted by injecting substances which are not subject to fast extravasation through the epithelial pores.

Higher molecular weight compounds exhibit a prolonged correlation time and, hence, increased relaxivity. In addition, larger molecules display a unique distribution characteristic: they do not diffuse into the extravascular space and thus are fundamentally useful as blood-pool contrast agents which demonstrate the perfusion characteristics of the area of interest. Using a suitable high molecular weight backbone such as albumin or polylysine, 50–100 gadolinium atoms can be incorporated in one molecule. Compounds with a relative gadolinium content of 20% (w/w) can be synthesized.

Several macromolecular, polymeric gadolinium chelates have been studied in animals including Gd-DTPA–albumin, Gd-DTPA–dextran, Gd-DTPA–polylysine and a Gd-

DTPA–polylysine substituted with methoxypolyethyleneglycol succinates.^{30–33} Such molecules with very high molecular weight, and consequently, larger size, are not subject to glomerular filtration and may stay in the blood or organism for a very long period of time. This disadvantage may be overcome by using biodegradable substances or molecules with matched molecular diameters which stay in the blood at high concentration sufficiently long to allow the diagnosis of tissue perfusion. After imaging, which may take place in the first minutes after injection, the compound may be renally excreted at a somewhat reduced filtration rate.

Gd-DTPA–polylysine is such a contrast agent with a tailored molecular size.³³ A Gd-DTPA–polylysine derivative with a molecular weight of approximately 40 000 results in a plasma relaxivity of about 14 L mmol⁻¹ s⁻¹ at 0.47 T, which is three to four times higher than that of Gd-DTPA.²¹ The resulting compound is highly stable and is soluble in water even at high gadolinium concentrations. Solutions of >0.1 mol L⁻¹ do not exhibit a major increase in the viscosity. Macromolecular structures may have a significant impact for the diagnosis of tissue perfusion and capillary integrity.

On intravenous injection, such a compound demonstrates a prolonged half-life in plasma. After distribution in the vascular system the agent is eliminated by renal filtration. By carefully selecting the size of the molecule, their molecular structure, and their chelating residues, it is possible to develop substances which undergo complete renal elimination without accumulation in the body and/or transchelation of the gadolinium ion. Determination of the tissue concentration of gadolinium showed that the polymer is distributed proportionally to the fractional blood volume and, therefore, reflects the differing degrees in the perfusion of different tissues.

Adverse reactions have been reported with the cationic polymer polylysine. When substituted with a Gd-DTPA derivative, however, the molecule loses the positive charge and displays an excellent tolerance profile. An LD₅₀ in mice of 17 mmol kg⁻¹ has been reported, a value significantly higher than that of Magnevist® (6–7 mmol kg⁻¹). Taking together both the increased relaxivity and the excellent tolerance of the substance, this contrast agent has a margin of safety superior even to that of low molecular weight compounds.

The blood-pool agent Gd-DTPA–polylysine is fundamentally suitable as an angiographic contrast agent. It allows the demonstration even of tiny structures of less than 1 mm diameter without the need for complicated subtraction procedures and scanning techniques, which are sometimes flow sensitive (Figure 3). This compound offers advantages not only in the differential diagnosis of tumors, but also, and in particular, in perfusion studies of the myocardium and pulmonary MRI. Recently, researchers from Boston reported selective accumulation of a Gd-DTPA–polylysine derivative in the lymphatic system.³⁴

Because of the high sensitivity of the contrast enhancing mechanism, only minor amounts of exobiotic substances are necessary to achieve a significant change in the signal intensity. Thus the selective targeting of receptors becomes possible using relatively small amounts of contrast agents. Channeling substances to the bulk excretory transporters located in the hepatocellular plasma membrane is a very efficient possibility to create highly liver-specific substances. Thus, higher local concentrations can be achieved by the use of derivatives of the Gd-

Figure 3 Contrast-enhanced MRI (2 T SISCO experimental MR imager) of a rat after intravenous injection of 100 $\mu\text{mol kg}^{-1}$ Magnevist® (top) or 25 $\mu\text{mol kg}^{-1}$ Gd-DTPA-polylysine (bottom). The IR-Turbo-FLASH sequence only demonstrates areas of very short T_1 relaxation times, thus producing a much longer vascular enhancement using the polymeric gadolinium chelate

DTPA complex such as GdBOPTA (gadobenate, Bracco, Italy) or Gd-EOB-DTPA (gadolinium-ethoxybenzyl DTPA) or the Gd complex of the disodium salt of (4*S*)-4-(4-ethoxybenzyl)-3,6,9-tris(carboxylatomethyl)-3,6,9-triazaundecanedioic acid (Schering AG, Germany)^{35–37} (Figure 4).

Gd-EOB-DTPA is a gadolinium complex with a lipophilic side chain attached to the DTPA backbone. The molecule, still ionic and extremely hydrophilic and water soluble, diffuses in

Figure 4 Chemical structure of gadolinium chelates used as liver-specific contrast agents in MRI

the extracellular space and is, at the same time, eliminated from the body both by glomerular filtration and hepatocellular transport mechanisms.^{36,37} Specific carriers of the hepatocytes ensure that this water soluble substance is transported into the hepatocytes and is, therefore, able to reach the intracellular water compartments and to shorten their relaxation times. As a result of this additional excretory mechanism such compounds become tissue specific, i.e. they demonstrate the healthy liver parenchyma selectively. On intravenous injection, a dose of less than 25 $\mu\text{mol kg}^{-1}$ bodyweight is sufficient to achieve selective enhancement of the liver parenchyma. Implanted tumors or metastases do not take up this contrast agent, but appear as low-signal structures and can be visualized better because of the increased contrast between the healthy liver parenchyma and the pathological area. Studies in rats demonstrated some uptake into hepatocellular carcinomas, depending upon the differentiation of the neoplasm. Gd-EOB-DTPA displays some transient protein binding either in plasma or in the cytoplasm of the hepatocytes. The protein binding ensures that the correlation time of the low molecular weight contrast agent is optimized. Such compounds do, in fact, have much greater relaxivity in plasma than in water. As a result, an increase in efficacy by a factor of 2 is possible.

Gd-EOB-DTPA exhibits favorable characteristics. In addition to its good diagnostic potential, the compound displays high solubility in water, high stability, rapid and quantitative elimination and, most important, a tolerance as good as Magnevist®. Clinical Phase I trials just recently conducted in Berlin by Schering AG (Dr. Th. Staks et al.) and the Radiological Department of the Free University of Berlin, Steglitz (Professor K. J. Wolf, and Professor B. Hamm) have demonstrated the excellent tolerance and imaging properties of Gd-EOB-DTPA (Figure 5). Doses as low as 10 or 25 $\mu\text{mol kg}^{-1}$ enhance the healthy liver parenchyma during a comfortable imaging window up to 2 h after bolus injection. The convenient complex is eliminated from the body in an unaltered form and in equal amounts renally and with the feces.

One of the ultimate goals of contrast agent research is to identify a tumor-seeking material. The high sensitivity and

Figure 5 Contrast enhancement of the human liver after intravenous injection of 25 $\mu\text{mol kg}^{-1}$ Gd-EOB-DTPA. The images (T_1 -weighted FLASH sequence, 1.5 T Magnetom, Siemens, Germany) for the Phase I study were obtained by Professor B. Hamm at the University Clinics of Berlin-Steglitz

excellent spatial resolution of MRI in combination with highly effective contrast agents may make the dream come true. Thanks to advanced biotechnology, the synthesis of tumor-specific monoclonal antibodies has become possible. Gadolinium labeled antibodies have produced tumor-specific enhancement in laboratory animals.³⁸ The feasibility of this approach to tumor-specific imaging has been demonstrated in a mouse study in which an implanted colorectal carcinoma was significantly enhanced at 24 and 48 h after administration of 2–3 mg gadolinium labeled tumor-specific monoclonal antibody.

Since most of the contrast agents administered do not accumulate in the tumor, the dose necessary to produce an adequate enhancement is still too high. Up to 10 g of a monoclonal antibody, each molecule labeled with dozens of paramagnetic ions, will be required to achieve diagnostically useful enhancement in man. Being tissue-specific, the contrast agents have to interact with biological structures and so lose their inertness. Special attention has to be focused on the tolerance to those materials in order to ensure that the diagnostic benefits are not obtained at the cost of a higher incidence of adverse reactions. However, it is very likely that clinical diagnostic imaging will be further improved by well-tolerated tissue-specific MRI contrast agents.

Relaxation Measurements in Imaging Studies

Margaret A. Foster

1 INTRODUCTION

T_1 and T_2 relaxation times of water or lipid protons vary between different tissues and pathologies, making them major properties in determining contrast within the NMR image. This has led to interest in the actual relaxation time values, in addition to their effects in 'weighting' images. Indeed, a number of investigators have looked for diagnostic or characteristic information from the diversity of relaxation values of normal and pathological tissues. In general, however, such numerical values have proved of more interest in research studies than as clinical tools. This is due to a combination of reasons including the variety of data collection techniques, the lack of true specificity of T_1 and T_2 for individual tissues and the wide and overlapping value ranges when pathologies are examined, see e.g. reviews by Bottomley et al.^{1,2} In addition, many of the techniques available on commercial imaging systems do not fully take into account the many technical difficulties in T_1 and T_2 measurement, resulting in poor relaxation time evaluation. This has been shown in several studies in which calibrated test objects have been imaged on several systems operating at the same frequency but have yielded results up to 100% different for a given value (see Section 4). Another important problem for clinical use of relaxation time values is the inherent difficulty in obtaining reliable tissue T_1 and T_2 values when applying MRI techniques to living subjects.

To obtain a T_1 or T_2 value from a small sample in vitro, the signal collection conditions can be optimized to remove many of the extrinsic factors which can affect the result. The sample is placed in a homogeneous B_0 field and is provided with one or more short, shaped rf pulses. The most commonly used pulse sequences for such measurements are, for T_1 , the Inversion-Recovery (IR) sequence ($180^\circ\text{rf}-\tau-90^\circ\text{rf}-\text{collect FID}$) repeated with variable τ_i (equivalent to TI in imaging) and for T_2 the Carr-Purcell-Meiboom-Gill (CPMG) sequence ($90^\circ\text{rf}(x)-\tau-180^\circ\text{rf}(y)-\tau-\text{collect spin echo}-\tau-180^\circ\text{rf}(y)-\tau-\text{etc.}$). In this latter sequence all the required data points can be collected after a single excitation, but for IR only one data point is collected per repetition of the IR sequence so adequate time must be allowed between sequences (TR) to allow complete relaxation to occur (normally >5 times the tissue T_1 value). In both cases a long train of signal size values can be collected to give sufficient data for a good quality analysis of signal size versus duration from the initial excitation. With such optimized methods and careful sample preparation, reliable, repeatable tis-

sue T_1 and T_2 values can be collected (see e.g. EEC Concerted Research Project, In Vitro Protocol³), with the major remaining questions relating to the nature of the information that is provided by these values. In NMR imaging, however, it is much more difficult to obtain high quality values.

2 IMAGING METHODS FOR T_1 AND T_2 DETERMINATION

During the early 1980s, attention was given to parametric mapping since it was felt that, in addition to the clinical value of pathology demonstration in parameter-weighted images, fundamental information about disease processes and useful classification of diseases might be obtained by quantitation of the parameters that yielded contrast in the weighted images. Attempts were made to obtain this information either by pixel-by-pixel calculated parameter maps or by calculations within regions of interest in images.

Most of the early attempts at T_1 and T_2 mapping used adaptations of the pulse sequences normally employed for in vitro studies, e.g. IR for T_1 mapping and CPMG, or repeated single spin echo sequences for T_2 . It was frequently felt that several points on the relaxation curve should be obtained, to improve the calculation (even when the calculation method assumed a single exponential relaxation process) and for both IR and single echo T_2 collections this implied long imaging times with the consequent problems of patient discomfort, movement, and misregistration artifacts. An increasing interest, therefore, developed in more rapid pulse sequences for this purpose. For T_1 this led to the use of Saturation-Recovery (SR) sequences with shorter TR intervals: results were obtained in a few minutes and so signal averaging could be employed to reduce noise leading to the suggestion of the greater 'efficiency' of SR over IR for T_1 mapping during an equal signal collection period.^{4,5}

Unfortunately reduction of TR has its own problems, especially relating to the slice profile (see later) which may degrade the accuracy of the results. Another approach to shortening the required time for T_1 and T_2 mapping was the development of multiple image collection strategies producing a short series of images of varying nature from which both T_1 and T_2 could be calculated (and often proton density as well),⁶ hence reducing the overall time of the patient in the imager (compared with the collection of separate image series for T_1 and T_2 calculation) and presumably also reducing misregistration artifacts. Such strategies may have improved the efficiency of parameter acquisition but did not necessarily improve the absolute accuracy, particularly if either the transverse or the longitudinal relaxation processes were not monoexponential, or if a short TR was used.

As the fast imaging sequences became readily available, possibilities for using these to provide T_1 and T_2 information were investigated. These studies still continue but often the results show little improvement in the overall ability to produce consistent and accurate T_1 and T_2 values, especially from living tissues, which offer a much greater challenge than does the simplicity of a paramagnetic metal ion-doped solution.

For both SR, in which a series of identical rf pulses are used to excite the system, and the IR sequence, in which the spin population is inverted along z by means of an 180° rf pulse prior to the rf pulse (which puts the spins onto the xy plane for measurement), the 'standard' form of the equation

showing expected signal size makes certain assumptions about the experimental procedures. For example it is assumed that the slice profile is a perfect rectangle, i.e. that all the spins throughout the slice are able to respond in the same way. As we will see, particularly in short TR sequences, this may not be a valid assumption. It is also assumed that all the spins are on resonance, but field inhomogeneities and local distortions due, for example, to susceptibility effects, may invalidate this assumption, hence affecting the calculated T_1 values. Also, in both cases, the signal may be obtained as a gradient (field) echo by reversal of at least one of the field gradients in order to rephase the spins, or by insertion of a 180° rf pulse after the main sequence, to produce a spin echo.

2.1 Saturation-Recovery

In its most basic form this sequence is: α_{rf} - TR - α_{rf} - TR -etc. where α_{rf} is the rf pulse required to produce a flip angle of α and TR is the interval between the centers of two adjacent 90° pulses. Such a sequence rapidly achieves the steady state situation and at this stage the signal size (M_S) of a gradient echo can be designated as

$$M_S = \frac{M_0[1 - \exp(-TR/T_1)] \sin \alpha}{1 - \exp(-TR/T_1) \cos \alpha} \quad (1)$$

if the following assumptions are made:

1. that the rf pulse is too short for significant T_1 relaxation to occur during it
2. that the flip angle is applied each time along the same axis with alternate phases
3. that the interval between α_{rf} and collection of the gradient echo is very short
4. that TR is considerably longer than T_2^* so that all transverse magnetization has dephased before each rf pulse.

Assuming that an accurate M_0 value can be obtained (e.g. by using this sequence with a TR much greater than the longest T_1 in the slice), a T_1 value can be calculated by rearrangement of equation (1). It has, however, been pointed out⁷ that a progressive inaccuracy will occur in such calculations if any residual transverse magnetization remains before the rf pulses. In cases where TR is less than or similar to T_2^* it is necessary to include additional terms involving $\exp(-TE/T_2^*)$ to take this into consideration or to make use of 'spoiler' gradients to dispose of any residual transverse magnetization before the next rf pulse. In addition, if the interval between the rf pulse and gradient echo is a significant proportion of T_2 , a term $\exp(-TE/T_2)$ must be included in the numerator to account for transverse relaxation during this delay. The equation for the SR signal with spoiler gradients then becomes (where TE is the interval between the rf pulse and the gradient echo)

$$M_S = \frac{M_0[1 - \exp(-TR/T_1)] \sin \alpha \exp(-TE/T_2)}{1 - \exp(-TR/T_1) \cos \alpha} \quad (2)$$

In proton imaging the use of a spin echo for signal collection is more frequent than that of a gradient echo. To attain this a 180° rf pulse is inserted after α_{rf} and a term similar to that used for T_2 effects in gradient echo collection in equation (2) is inserted to allow for T_2 relaxation that has occurred during

TE (in this case the interval between the center of the α_{rf} pulse and the center of the spin echo). Additional terms are required when TE is a significant proportion of T_1 to allow for the shift in origin of the T_1 recovery.

2.2 Inversion-Recovery

This sequence basically consists of: 180° rf- TI - 90° rf-(echo)- 180° rf- TI - 90° rf-(echo)-etc., where the dominant time intervals are the repetition time, TR , and inversion interval, TI . Both of these can be manipulated to put T_1 information into a signal. In the most basic form, the signal size is expressed by

$$M_S = M_0 [1 - 2 \exp(-TI/T_1) + \exp(-TR/T_1)] \quad (3)$$

(inversion effects) (saturation effects)

Once again this is multiplied by $\exp(-TE/T_2)$ for a spin echo collection. This sequence has been used in experiments where strong T_1 contrast is required and in particular with short TI intervals for rapid imaging, e.g. the short tau IR (STIR) sequence.⁸ For calculating T_1 values the sequence would normally be used with a long TR and repeated with varying TI intervals. A plot of signal size against TI yields the T_1 value of the tissue in a voxel. However, obtaining adequate numbers of images for an accurate T_1 plot can take an hour or more and the tendency has been, therefore, to reduce the procedure to a two-point determination, i.e. to extrapolate a T_1 value from two points on the relaxation curve. A similar approach⁹ has been to interleave the IR sequence with a long TR SR sequence to provide an M_0 value and calculate the T_1 , assuming a single exponential relaxation, from M_0 and one point affected by T_1 relaxation. The accuracy of such an approach, as for all versions of the SR and IR sequences, is dependent on the use of perfect 180° and 90° pulses^{10,11} (the 180° pulse is replaced by an adiabatic fast passage inversion by Edelstein et al.⁹ which may bring in complications, e.g. arising from magnetization transfer effects), and a truly monoexponential relaxation for the T_1 process. Some allowance can, however, be made for imperfect rf pulses if a sufficient number of images are collected to allow a three-parameter fitting procedure to be applied to the data. The fit is of the form¹²

$$S(TI) = A + B \exp(-TI/T_1) \quad (4)$$

where A and B can take into account imperfections in the rf pulses. Unfortunately collection of sufficient data takes a considerable amount of time.

Since the duration of the collection time is a major problem for both SR and IR sequences, when used for T_1 mapping, attempts have been made to reduce the necessary time by obtaining the relaxation time data from limited regions within the slice, rather than over the full slice area. For example, Morone and co-workers^{13,14} have proposed a method for obtaining T_1 data from a strip through the image. The method, which employs a selective 180° rf pulse to distinguish the strip, results in a slightly reduced signal-to-noise ratio but this can be improved by signal averaging without losing all of the collection time improvement.

2.3 Variable Flip Angles

One method that has been tried for shortening the time required to obtain a full T_1 map using the SR sequence is the use of variable flip angles.¹⁵ From equation (2) it can be seen that the signal for the SR sequence (with gradient echo collection: spin echo cannot be used here because of the transverse rephasing due to the 180° rf pulse) can be modified by varying either TR or the flip angle α . If TR is kept constant, and a series of images collected with different α , T_1 (on a pixel basis) can be calculated as a linear regression of $I\alpha/\sin \alpha$ vs. $I\alpha/\tan \alpha$, where $I\alpha$ is the signal intensity from the collection using flip angle α . This relationship is directly derived from equation (2) and is a straight line with slope $\exp(-TR/T_1)$. Since the slope depends only on TR and T_1 , T_1 can be calculated without needing a value for the equilibrium magnetization (M_0), hence saving considerably in collection time. In addition, TR can be kept short, thus adding to the time saving. Unfortunately the technique is particularly sensitive to artifacts due to magnetic field inhomogeneities, inflow, and changes of the slice profile when short TR is used.¹⁶ It is also very sensitive to errors in the flip angle used.¹⁷

2.4 Spin Echo Sequences

Discussion of the above sequences has mainly been directed toward T_1 measurement. In fact, T_2 is also available from SR and IR images collected with a spin echo, by manipulation of the TE intervals whilst maintaining TR and TI constant. In such cases the influence for variation between the images will be the T_2 decay given by the term $\exp(-TE/T_2)$ shown in equation (2). T_2 can be calculated from two or more images in the same way and with the same assumptions and restrictions as shown for T_1 . Such methods are the basis for the integrated T_1/T_2 /proton density collection strategies mentioned earlier and are discussed in detail, along with the necessary data analysis technique, by Bakker and de Graaf.¹⁸ Where a T_2 value is calculated from two separate echoes, however, the result may be heavily affected by diffusion processes.

When T_2 is required alone, or in greater detail, a multiecho sequence such as the CPMG is normally chosen. An image of different T_2 -weighting can be produced from each, or from selected echoes of the train and T_2 can be calculated from these on a pixel-by-pixel basis. In some cases, multiecho sequences have been extended over a considerable period, allowing accumulation of sufficient points on the relaxation curve for bi- or even multiexponential analysis, separating the T_2 values of several relaxation components represented within the overall curve. Such techniques have been the basis for studies in which different components are assigned to different tissue elements within the overall organ.¹⁹ Problems may, however, arise in such signal collections from pulse imperfections and incorrect rephasing of the signal.

2.5 Stimulated Echoes

The T_1 techniques discussed so far have required the collection of at least two independent full or partial images (although these may be from a combined image collection procedure). Methods do exist, however, to collect information from several points on the T_1 relaxation curve after a single excitation,

hence considerably reducing collection time. One method for achieving this involves the use of stimulated echoes in which an image is created by the application of three 90° rf pulses.²⁰ This can be shown as

in which the initial 90° rf pulses are used to store a part of the magnetization longitudinally. This decays according to T_1 and the decay is sampled, after time TM , by the third pulse. The signal intensity of the echo is given by

$$M_S = M_0[\exp(-TE/T_2) \exp(-TM/T_1)] \quad (5)$$

Hence by varying TM , a series of signal values can be obtained with different T_1 weightings. If, however, a chain of rf pulses of variable flip angle is inserted in place of the third 90° pulse, the technique becomes a single-shot method which yields the T_1 information directly.²¹ The sequence is now

where i is the number of repeats in the train of limited flip angle rf pulses, each of which is followed by an echo acquisition. Each limited flip angle rf pulse samples the decay of the longitudinal magnetization by tipping out a small transverse component of it (TM increases for each sampling). The complete i set of rf pulses, with the final one being 90° , gives a series of values along the T_1 relaxation curve.

The method has the advantage of speed and it also provides a large database for the T_1 calculation, since i can be a substantial number. The method does, however, suffer from the major disadvantage that a stimulated echo gives only 50% of the maximum available signal strength, hence reducing the efficiency of the technique.²²

2.6 Look-Locker Sequences and TOMROP

The NMR and ESR spectroscopy sequence proposed by Look and Locker²³ also uses a series of limited flip angle pulses to sample the T_1 relaxation curve after a single excitation. A 180° inverting pulse is followed by a train of closely spaced, equal amplitude, limited flip angle rf pulses which forces the magnetization to evolve toward a new equilibrium state. The signals acquired from this represent points along the T_1 relaxation curve which, for this sequence, has the appearance of a normal inversion curve ($-M_0$, through zero to $+M_0$) but with a set of 'saw-teeth' superimposed upon it due to the low flip angle pulses. There can be a substantial number of these pulses (e.g. more than 32 even in imaging) and each one provides information about the relaxation at a different time after inversion. Hence a 32 (or more) point T_1 relaxation curve can be produced in the time normally required for the collection of a single TI point with the normal IR procedure. The concept has been developed into an imaging technique²⁴ and has given rise to the TOMROP (T One by Multiple Read Out

Pulses) method.²⁵ The signals are collected as gradient echoes, and the dynamic range of this procedure is much greater than that of the one-shot stimulated echo method.²² The technique, however, does suffer from the disadvantage of a low signal-to-noise ratio due to the low flip angle of the pulses used for signal collection. Despite this, it still represents a reliable and fast method for in vivo T_1 mapping.

2.7 Echo Planar Imaging Methods

Echo planar imaging (EPI)²⁶ allows extremely fast image acquisition. An early attempt at obtaining T_1 from echo planar images involved varying the delay time between image collections. The longitudinal signal component decays during this delay period, so collecting signals after varying delay times inserts T_1 information into the images.²⁷ A two-point T_1 map can be produced rapidly from a sequence of three EP images. The authors point out, however, that there are problems with the method which lead to systematic errors in the calculated T_1 values. A later technique by the same group²⁸ involved the insertion of a 180° inverting rf pulse immediately before the collection of the EP image. One image is collected after each inversion and this image has the T_1 contrast related to the inversion-recovery time before its collection. A series of such images can, therefore, yield the T_1 relaxation curve. This technique has the advantage of very high speed acquisition of the T_1 information but suffers from problems related to the spatial resolution of EPI and to low signal-to-noise ratio. It is also very sensitive to magnetic field inhomogeneities.

2.8 Snapshot FLASH Method

This technique employs the FLASH (Fast Low Angle SHot) technique²⁹ in which a train of low flip angle rf pulses are employed with a very short TR between them. The signal is collected as a gradient echo with a very short echo delay time. Recent developments of the FLASH technique (to snapshot-FLASH) have brought the image acquisition time down to 200 ms for a 64×128 pixel image.²⁹ The technique has been developed as a quantitative T_1 imaging method in which, by use of TR values of less than 10 ms, the total imaging time is less than an average tissue T_1 value. T_1 information is provided in the same way as in IR-EPI, by the insertion of an inverting 180° rf pulse before the snapshot-FLASH imaging sequence. During the inversion-recovery of the longitudinal magnetization, several IR-weighted images can be obtained which show dynamic changes of contrast relating to the time since the spin inversion. T_1 values can be calculated on a pixel basis using a three-parameter fit. This technique is the fastest T_1 imaging technique proposed to date and gives accurate T_1 values compared with known standards.³⁰ Certain problems still need to be addressed, however. For example spatial distortions may occur in the images due to effects on the point spread function arising from the 'inversion-recovery' during the imaging period²⁹ (the pixel is broadened by more than one-pixel diameter if the measuring time is equal to the T_1 value). Also of importance may be the T_1 relaxation which occurs during the acquisition of each of the snapshot-FLASH sequences following the spin inversion. The FLASH acquisition requires approximately 200 ms for the full image. This, however, can be a significant pro-

portion of the T_1 relaxation time of certain tissues, particularly if the method is used at lower magnetic field strengths. The effects of this on the T_1 weighting of the image need to be assessed (the same problem is true for IR-EPI).

Snapshot-FLASH can also be used to obtain T_2 information by preceding the FLASH sequence by a spin echo preparation (e.g. of the DEFT type) rather than by an IR pulse. Limited tests have shown that such a sequence can produce acceptable values.

3 PROBLEMS IN OBTAINING T_1 AND T_2 VALUES IN IMAGING

As will have been seen from comments whilst discussing the various methods for T_1 and T_2 estimation, there are a wide variety of problems to be overcome before any imager-derived value can be regarded as acceptable. Only a few of these can be highlighted here, with the majority of the discussion relating to the longer collection sequences which have been more fully examined and tested.

Some of the major problems encountered when measuring relaxation times in vivo are:

1. magnetic field inhomogeneity effects, including those due to the field gradients,
2. slice profile effects, related to pulse sequence timing etc.,
3. problems relating to rf pulses and signal phase,
4. errors when multislice collection procedures are used,
5. misregistration problems when T_1 and T_2 are calculated from several image data sets,
6. partial volume effects due to tissue inhomogeneity,
7. assumptions made in the T_1 and T_2 calculation, e.g. regarding relaxation monoexponentiality,
8. a wide variety of effects arising from the living tissue/body itself, such as flow, diffusion, magnetic susceptibility, etc. which can all either affect the relaxation time value directly or alter the apparent place from which the information is coming.

The extent to which any of these problems will distort calculated T_1 and/or T_2 values is dependent on interactions between the properties of the tissues in the slice, the imaging technique being used, and the precise nature and timings of the pulse sequence being applied.

3.1 Magnetic Field Inhomogeneities

An automatic assumption in all signal size or relaxation time calculations is that all the spins in the sample (i.e. one voxel, or all the voxels to be averaged together in a single region of interest) have the same resonance frequency and hence are able to respond in exactly the same way to each rf or gradient field manipulation. If the applied magnetic field is inhomogeneous for any reason, the proton Larmor frequencies will be different in different regions of the sample. Modern magnet technology has helped reduce the scale of this problem as it relates to the applied static (main) field but in all MR imaging, the spatial information is obtained by the application of one or more magnetic field gradients. This automatically implies that the sample will experience a spread of B values and hence of Larmor frequencies. Although carefully shaped rf pulses of

appropriate bandwidth can reduce the effect, there will inevitably be some reduction in the precision of relaxation time measurements due to the statistical spread of the values.

3.2 Slice Profile Effects

In some ways this problem is a continuation of the above, in that the effect arises from the lack of ability of the entire spin population to respond equally to the manipulation. In this case, however, inaccuracies originate from saturation effects developing during the selective excitation that defines the image slice.¹⁶

An increasing need to obtain the NMR image rapidly has led to the almost universal use of TR times that are short in relation to the time necessary for full longitudinal relaxation. In such a case, if there is any deviation (which is always the case) from a 'perfect', i.e. completely rectangular, slice profile, saturation effects will demonstrate themselves as variations in the flip angle through the width of the image slice. To demonstrate this let us take a 'worst case' situation in which a Gaussian rf pulse is applied, yielding a Gaussian-shaped slice profile. On first application of the slice selective rf pulse, the spins in the center of the slice thickness receive, say, a 90° flip, but those toward the edges will be flipped by progressively less than this. With a sufficiently long TR all the spins will completely relax and the overall effect will be that the spins on the outer edges of the slice width contribute less to the signal from the voxel than do those in the center. In itself this is a source of error but is less significant than that arising when TR is short. In this case, relaxation is incomplete so at the next excitation the spins at the edges, which have had less relaxing to do, will have returned fully to the preexcitation state and further excitations will induce a contribution to the signal which is the same as that at the first excitation. The spins in the center of the slice, however, have further to relax and will not have completed their relaxation during TR , so the next excitation, which returns these central spins to the xy plane, will operate on a partially saturated population. These spins, therefore, will make a smaller contribution to the overall voxel signal. With TR values that are substantially shorter than the T_1 of the material in the voxel, this can lead to a slice profile that has a considerable dip in the middle and 'horns' at either side. Two types of error arise in this situation. Firstly the information is not coming evenly from where it is expected. Secondly, and most important, the effect causes inaccuracy in the actual calculation of the relaxation time, to an extent dependent on the nature of the pulse sequence and calculation method.³¹

3.3 Rf Pulses and Signal Phase

Problems that may arise due to imperfect rf pulses (i.e. inappropriate flip angles being produced) have been highlighted during the discussions of the pulse sequence types. The extent of sensitivity to such effects is very closely related to the nature of the particular pulse sequence. In addition, some pulse sequences may be very sensitive to phase errors which accumulate as the sequence is repeated during the image acquisition procedure. The dependence of the calculated T_1 value on the accuracy of the 180° pulse has been calculated for an interleaved SR/IR sequence.³¹ In a case where the slice selection rf pulse is assumed to be an accurate 90° and the slice profile to be a perfect

rectangle, it was shown that varying the angle of the inverting rf pulse from 180° to 150° produced a systematic error in the measured T_1 value. For actual T_1 values comparable to the TI of the simulated sequence, the 150° 'inversion' produced T_1 values that were 5% lower than expected, but the difference rapidly increased for longer T_1 values, producing e.g. a value of 750 ms when the true value was 1 s and TI was 200 ms. Inaccuracies in the 180° and 90° pulses may arise from instrumental factors but can also be due to rf power absorption in the body,³² and hence may vary from patient to patient or even between tissues of the same individual.

3.4 Multislice Collection

Increased pressure for more rapid MR image acquisition has led to the almost universal introduction of multislice techniques. This can, however, lead to extensive problems if specific parameters such as T_1 and T_2 are being calculated. Several workers have emphasized the potential inaccuracy of T_1 values when these are calculated from slices other than the first one in a multislice acquisition.^{33,34} They have particularly highlighted the fact that the measured ' T_1 ' value depends on the width of the gap between the slices. Such findings are consistent with the suggestion by Dixon et al.³⁵ that the frequency selection rf pulse, in the presence of the field gradient used to select a particular slice, acts as an off-resonance pulse in neighboring slices in which the protons are experiencing different levels of the field gradient and, therefore, have different Larmor frequencies. Such effects are, of course, observable only in tissues or gels and are not seen in the paramagnetic metal ion solutions that are usually used to calibrate relaxation time measurements.³⁶ In addition, since different tissues show different amounts of magnetization transfer (which is the basis for the use of MTC to enhance image contrast) the T_1 values will be distorted to different extents. From this it is obvious that T_1 measurement must be a single-slice experiment.

Accurate T_2 estimation is also problematic during multislice collects.²² If the slices are contiguous, unwanted echoes can be produced at the slice edges, distorting calculated parameter values.

3.5 Misregistration

This problem arises when T_1 and T_2 values are calculated from several image data sets. The relaxation time value(s) are calculated either on a pixel-by-pixel basis to form a parameter map or from a group of pixels forming a region of interest. Since the individual images represent points on the relaxation curve, it is obviously essential that they come from the same sample of tissue (or test object). If, however, the patient moves or the imager slightly changes its performance during the serial image collection, then any specified pixel may contain different material before and after the move. Any relaxation time values calculated from the signal intensity of the two pixels would, therefore, be completely misleading. When homogeneous test objects are studied, this effect will only be of importance close to the edges of the objects, but if an organ of complex geometry is studied, e.g. white and gray brain tissue, then any slight movement, in any direction, could result in erroneous values.

This problem is difficult to overcome if several images are required to be collected sequentially, each with a substantial

TR. For two-point longer *TR* sequences the most successful approach has been that of interleaving the signal collection. For example, one sequence for producing a T_1 map³⁷ employs one SR and one IR image. These are collected together using a compound SR/IR sequence. In this way any movement or imager changes occur equally, and simultaneously, to both image collections, and misregistration between pixels of the two images is prevented.

3.6 Partial Volume Effects

This is a problem met in all forms of imaging. In a large, homogeneous test object, regions for T_1 and T_2 estimation are available in which the entire voxel is filled with the same material. This is almost never the case in the living body. Obvious examples of this can be seen in the brain, where the gray brain tissue is a thin layer over the white matter, in intimate contact with it (and also with cerebrospinal fluid; CSF). In such a case, a high proportion of voxels in the general gray matter regions will also contain, in variable amounts, white matter and/or CSF. Attempts have been made to sort out the tissues in such cases, often by multiexponential analysis of the relaxation curve. Success is usually limited, however. Often the 'partial voluming' is more subtle than this, with the mix being at the cellular level. For example, liver tissue, occurring in large lobes in the abdomen, gives the impression of being an ideal subject for relaxation time measurement because of its apparent homogeneity but this appearance is deceptive. In the general regions of the lobes (i.e. away from the attachment areas), the liver comprises two major cell types: about 80% hepatocytes and 10% Kupfer cells (the latter are part of the reticuloendothelial system). The rest is a mixture of cell types forming blood and bile vessels, etc. It may be assumed that all these cell types have different T_1 and T_2 values which average together to produce the 'normal' figure. In different parts of the liver, however, the cellular proportions can vary considerably, giving subtle differences that are, nonetheless, directly equivalent to partial volume effects between two adjacent tissues.

3.7 Calculation Method

Only under exceptional information collection conditions are sufficient data points available along the relaxation curve to allow bi- or multiexponential analysis. In the great majority of imaging T_1 and T_2 experiments, the data are more sparse and have to be analyzed as a single exponential. The crudest methods for this are when only two data points are available: for T_1 these are normally the M_0 value obtained after a single 90° pulse and one point along the relaxation curve. Under perfect conditions, if the relaxation really is a monoexponential relaxation, the value can be calculated accurately from these points. However, as pointed out with the list of problems above, many factors can distort the measured data points. Fundamentally a 2-point method has to 'use' all the information of those two points, so any form of inaccuracy in either point (e.g. delay in sampling so that relaxation has started before the M_0 measurement is made or noise affecting either point) will have a direct and fundamental effect on the calculated result. If, however, a third point (i.e. another image with a different T_1 weighting) can be added, then the total reliance on each point is reduced, and adding further points progressively helps; this, of course, is only

true if the adverse effect results in random effects on the signal. Where it is systematic, no improvement in the number of points will necessarily help to improve the accuracy of the calculated value. The effects of noise on these signals have been analyzed by Kurland.³⁸ One of the major advantages of the rapid, single-shot techniques is that they can produce a large number of data points along a single relaxation curve, hence improving the accuracy of the T_1 and T_2 calculations.

Not all tissues exhibit monoexponential relaxation behavior. For most tissues, T_1 relaxation, within the limits detectable by most imaging methods, is generally considered to approximate to a single exponential process unless there are proton populations which are not in fast exchange (e.g. the lipid and water protons in adipose tissue). In these cases multiexponential T_1 behavior can be observed. T_2 is a more complex phenomenon and, depending on the way the experiment is performed, a high proportion of body tissues show multiexponential relaxation.

Biexponential fitting procedures, to be reliable and repeatable, require a considerable number of data points in the curve: the more points (spread over a substantial part of the total curve) the better the chance of obtaining a good separation of the two exponentials. The precise ability of any separation algorithm will depend upon:

1. the number of data points and their spread
2. the amount of noise on the signals
3. the separation between the two T_1 and T_2 values: it is easier to separate two values that are very different (i.e. 100% or more) than similar ones
4. the amount of each spin population that is present: if the population contributing one T_2 value accounts for only 10% of the total signal, it will be more difficult to separate out than if the two populations are more similar in their contribution (i.e. magnitude).

All the above points govern the chances of success of any biexponential fitting procedure, whether this is the relatively crude method of 'curve stripping' in which the long T_1 or T_2 component is isolated and then deducted from the overall curve to leave the short relaxing component (a method which is extremely sensitive to noise), or whether a more elaborate, iterative, 5-parameter fitting technique is used. All the requirements become even more demanding if attempts are made to separate more than two exponentials, and the problem becomes computationally very demanding.

3.8 Biological Effects

There are a wide range of biological parameters and tissue interactions that can influence the measured relaxation times. For example distorted T_1 and T_2 values can arise due to flow and perfusion effects, diffusion, especially where this is anisotropic, e.g. in oriented tissues such as muscle or nerve tracts, magnetic susceptibility differences between tissues, etc. A full discussion of these effects is outside the scope of this article but most of the biological factors can be seen as changes in the local magnetic field so that the spins in a voxel can no longer be regarded as a homogeneous population, or due to movement of part or all of the spin population during the data collection period so that the signal from the same pixel in different images no longer arises from the same spin population. A very good example of the effects of life processes on measured tissue relaxation time is

provided by Katz et al.,³⁹ who looked at T_2 measurement from myocardium. They demonstrated differences between in vivo and ex vivo T_2 values in this tissue and also showed the variability of the in vivo measurements and their relationship to factors such as the velocity of movement of the cardiac wall.

4 THE VALUE OF CALIBRATION

We have emphasized the methods for, and problems in, direct measurement of T_1 and T_2 when using imaging techniques. The problems are indeed so great that, for longer TR methods at least, the use of 'dead reckoning' techniques (i.e. direct signal acquisition and calculation of the relaxation times from the basic equations), except over limited ranges on certain specifically designed MR imaging systems, can produce very misleading results. Even the use of manufacturer's recommended methods, which often include the use of 'look-up' tables rather than full calculation, can produce erroneous results. This has been demonstrated, for example, by the EEC Concerted Research Program⁴⁰ in which a set of carefully prepared test objects were imaged on a number of MR imagers sited throughout Europe. The test object for T_1 and T_2 testing consisted of a set of gadolinium (Gd)-doped agarose gels of known relaxation time values and with known frequency-dependence characteristics. The Gd/agarose mixtures were chosen to cover a wide range of T_1 and T_2 values and ratios between these parameters, so that a close match to tissue properties was obtained. The various imagers were tested using their own procedures for acquisition and calculation and enormous variability was found in the ability to produce accurate results. The responses ranged from acceptable accuracy over at least part of the relaxation value range, to systems which gave a virtually flat response, i.e. produced the same parameter value whatever the actual value of the gel being tested. Such studies show that reliance on manufacturer's built-in procedures can lead to inaccuracies as great as those produced by 'dead-reckoning'.

Perhaps the best method to improve the accuracy of imager T_1 and T_2 values is by appropriate calibration. If a reasonable range of doped gels or solutions is examined by detailed relaxometry at the appropriate frequency and temperature, and these 'real' values are compared with the T_1 and T_2 values obtained for the same samples on the MR imager, a calibration curve for each relaxation time can be produced, against which the tissue values can be corrected. This will help to remove systematic errors in T_1 and T_2 measurement, as seen in the study of MacFall et al.⁴¹ Even this, however, will not remove all the difficulties met when living subjects are examined. As already mentioned, the flip angle produced by the rf pulse will vary in different individuals and for different tissues in the same individual. In such cases, calibration will not be of help in improving accuracy.

5 CONCLUSION

Measurement of T_1 and T_2 values, using MRI methods and equipment, and especially when attempted on living subjects rather than small, static test objects, is not easy and can be very inaccurate. Variations in the measured or calculated values may be induced by a wide range of machine and sample variables and even careful calibration can only partially help in

reducing the inaccuracies. These difficulties and potential inaccuracies have led to considerably reduced clinical interest in obtaining this quantitative information. It is still possible, however, that studies of relaxation behavior could provide information leading to better tissue characterization and even to an improved understanding of some aspects of disease processes. With this in mind, therefore, we can hope that future developments and validation of the very fast, single-shot techniques for relaxation time measurement will restore confidence and interest in this quantitative aspect of MRI.

Relaxation Measurements in Whole Body MRI: Clinical Utility

Peter A. Rinck

University of Mons-Hainaut Medical Faculty, NMR Laboratory,
Mons, Belgium

1 INTRODUCTION

The use of relaxation times for medical applications was first proposed, attempted, and patented in 1974 by Damadian and collaborators.^{1,2} Originally, Damadian did not intend to use the relaxation times for imaging but for tissue characterization. The method was aimed at screening humans for cancer cells. This idea has since occupied the minds of many researchers, as the ultimate goal of diagnostic medicine is noninvasive tissue characterization and the external identification of malignant cells within the human body without touching the body. Damadian's claim that relaxation time changes highlight cancer cells seemed to be the pivotal step in medical progress. Thus, it is understandable that relaxation has been described as the Holy Grail of magnetic resonance. Damadian's assertion that NMR can detect cancer has proven partly true, but in a different way: MRI with images based on relaxation times has become one of the main medical technologies applied in cancer diagnosis and follow up. In clinical routine, relaxation time measurements are not used for this purpose.

2 METHODS

2.1 In Vitro Determination of T_1 and T_2

High-resolution magnetic resonance spectroscopists have measured T_1 and T_2 values for more than four decades. The in vitro measurement is done on a small sample, approximately 0.1–1.0 ml or larger in volume, in an extremely homogeneous magnetic field. Usually, the measurements are performed at

relatively high magnetic field strengths compared with those used for clinical MRI.

A variety of methods has been developed to obtain maximal precision with minimal time consumption. Typically, 15–30 magnetization measurements are performed on the sample for different time delays (TI and/or TR) using inversion recovery (IR) or saturation recovery (SR) pulse sequences. Based on these results, an observed T_1 value is calculated. Usually the error limits are better than 5%.

T_2 can be calculated with a single multiecho sequence. The more echoes one uses the more accurate the measurement will be.

2.2 In Vivo Determination: Localized Measurement

For magnet systems with larger bores, it is possible to examine whole organisms. One of the major problems of in vivo relaxation time measurements is the localization of the volume to be observed. Details of such localization techniques are given elsewhere in this book. The actual accuracy of in vivo measurements depends on the number of points acquired and the quality of localization.

2.3 In Vivo T_1 and T_2 Images

The current method used to obtain a T_1 image, i.e. an image whose picture elements represent pure T_1 values, relies on a mathematical manipulation of separately obtained images with different T_1 influence. In clinical surroundings, typically two to four images are used. Bearing in mind that in vivo relaxation can be multiexponential, it is somewhat inadequate to perform the analysis by such a limited fit to an exponential curve. T_2 images are calculated from the images of a multiecho series. Both methods can be combined into mixed sequences such as the one described in Figure 1.³

All methods relying on slices through the examined object will have as additional error sources, among others, partial volume effects from the edges of the slices and inaccuracies created by the slice profile. The only method that avoids this slice problem is the true three-dimensional (3D) volume imaging method. Still, in vivo relaxation time values can only be considered as estimated values.

Recently, progress has been made in using rapid imaging sequences to measure T_1 ; such techniques may prove useful e.g. for estimating the concentration of paramagnetic contrast agents in an organ.

Figure 1 Timing of a mixed sequence for the in vivo determination of T_1 , T_2 , and ρ values in a whole body MR machine

2.4 T_1 (T_2) Images and T_1 - (T_2)-Weighted Images

In clinical routine, people often talk about T_1 , T_2 or proton density images. The correct terms should be T_1 -weighted, T_2 -weighted, and *proton density-weighted* (or better: *intermediately-weighted*) images, because these images have only a certain T_1 , T_2 , or proton density dependence. However, they are not calculated pure relaxation time or proton density images.

3 PROBLEMS

The original idea of replacing hospital pathology departments by MRI equipment did not materialize. In vivo relaxation time measurements based on MRI have been tried over the years by a large number of researchers who used relaxation time values for tissue characterization in the brain, body, muscles, and bones. The task proved to be in vain because all efforts to characterize or even to type tissues largely failed. The reasons are manifold and include systematic measurement errors, inaccuracy of two-point plotting methods of relaxation curves, inherent variability of tissue composition, partial volume effects, and interobserver variability. Researchers realized that it is futile to measure a point or a region of interest within a tumor because too many different components, such as tumor and necrotic cells, small vessels, calcifications, and other structures, can be found within a volume of interest (see Figure 2).

In addition, T_1 and T_2 values overlap with those of other pathologies and sometimes of normal tissue, and T_1 and T_2 values of normal tissue change with age and hormonal cycles, breast tissue being a good example.

In 1985 Rinck et al. demonstrated that even carefully performed in vivo T_2 measurements are nondiagnostic in cancer detection, characterization, or typing.⁴ After absolute T_1 and T_2 values had been used unsuccessfully by researchers, combinations of T_1 and T_2 , histogram techniques, and more

sophisticated 3D display techniques of factor representations were used.⁵ However, the heterogeneity of normal tissues, as well as that of pathological benign and malignant tissues, did not allow the pathologist's view through the microscope to be replaced with MRI techniques. Thus, for tissue characterization new techniques have been proposed which are not based upon relaxation time measurements.⁶

Damadian also claimed that T_1 values of tumorous tissue are always higher than those of normal tissue. His dream of MRI becoming the perfect screening method for cancer tissue in the human body was finally shattered when this claim was refuted. T_1 values depend on the magnetic field strength, i.e., they increase with the magnetic field. Some tumor values can be lower than the values of normal tissue at certain fields; some are even the same at certain fields so that they cannot be distinguished.⁷

4 APPLICATIONS

Every year, the literature announces new attempts to exploit relaxation time measurements in vivo. There are some positive reports about the successful use of relaxation time measurements in vivo. These all concern follow up of therapy with patients being their own reference. Publications include, for instance, the report that relaxation times from leukemic bone marrow can be used for the differential diagnosis of this disease.⁸ Similar results in high-grade gliomas were published by another research group.⁹

Another quite interesting relaxation time study is the measurement of normal-appearing white brain matter in multiple sclerosis (MS) patients. Not only MS plaques but also the inconspicuous-looking white matter are changed by the disease. Relaxation time measurements revealed generally longer T_1 and T_2 values than in normal subjects. Pixel-by-pixel mapping suggests that there might be minute invisible changes in the white matter which might explain brain function deficits not explainable by the size and location of visible MS plaques.^{10,11}

When magnetic resonance began to be used for medical purposes, it was thought that relaxation times could help to distinguish between tumors and normal tissue since most T_1 (and in a similar way, T_2) values of pathologic tissue can differ markedly from the T_1 of similar normal tissue.⁴ But the ability to discriminate, type, or even grade tumors using relaxation time values has remained a dream despite the sophisticated multipoint fits introduced over the years.

Figure 3 shows that there are differences between T_2 values of normal and diseased tissues. Although T_2 values are more accurate than those of T_1 because more points are used for their calculation, there are no significant differences between the T_2 values of e.g. tumors and demyelinating disease or infarction.

This overlapping is due to variations within the same lesion related to vascularity, necrosis, and cell behavior. Similar lesions may have more than a single exponential relaxation rate, e.g. brain tumors and MS plaques. This is not unexpected, considering the heterogeneous nature of tumors. Furthermore, matrix size and slice thickness, i.e. partial volume effects, are limiting factors in relaxation time measurements in vivo because of the many different biological structures within one volume element. Standard deviation in fitting, artifacts, and

Figure 2 Malignant brain tumor. Relaxation time measurements in vivo can be performed pixel-by-pixel and by regions of interest of different size (left: small regions of interest covering edema, tumor, necrosis, etc.; right: large regions covering the entire tumor). Partial volume effects and other factors influence the measurements and contribute to inaccurate values. (Reproduced by permission of Blackwell Scientific, Oxford, from Rinck¹⁶)

Figure 3 T_2 values of different normal and pathological brain structures. (Reproduced by permission from Rinck et al.⁴)

variations in the selection of volume elements by the operator are all possible sources of error. System changes over time add to the uncertainty. Therefore, the follow up of treatment based upon relaxation time values is difficult and in most instances dubious (Figure 4).

The availability of databases of in vivo relaxation time measurements is very limited. The largest collection of data was published by Bottomley et al.^{12,13} A comparison between in vivo and in vitro relaxation measurements is quite difficult because many T_1 relaxation time values change rapidly after excision. Only brain tissues reveal a relatively stable relaxation behavior after they have been removed from the body.¹⁴ As with T_1 , pure T_2 images or techniques such as T_2 profiles through parts of the body do not increase the specificity of clinical diagnoses.

5 FIELD CYCLING RELAXOMETRY

An area of relaxometry which developed specific medical applications in the second half of the 1980s is field cycling relaxometry. This technique requires a special NMR machine, the field cycling relaxometer. With this machine, ex vivo or in vitro measurements of the relaxation behavior of tissue samples or contrast-enhancing compounds can be performed at any field strength.

The advantages of this method are obvious: (a) identical samples can be examined under identical conditions; (b) there is no interference by motion, diffusion, perfusion, flow, imaging artifacts, partial volume effects, or interindividual variations in region-of-interest/volume-of-interest delineation; (c) exact multiple-point fits are possible; (d) the entire field range used for MRI can be covered; and (e) the standard error is less than 3%. Field cycling relaxometry showed that T_1 increases nonuniformly with field, leading to specific fingerprints of T_1 increase for different tissues.

Figure 4 (a) T_2 relaxation time measurements of identical samples under identical measurement conditions which can reveal large standard deviations as shown in this example.¹⁷ (b) Relying on in vivo measurements to evaluate the outcome of treatment is dubious. Only in some instances do massive changes allow a positive assessment (Reproduced by permission from Rinck¹⁷ and Jensen et al.⁸)

It also showed that T_1 contrast for brain tissues is best at low/medium field.^{7,14} The pivotal benefit of such relaxation time or relaxation rate ($R_1 = 1/T_1$ and $R_2 = 1/T_2$) measurements is to allow the prediction of image contrast and the development of more specific contrast agents.^{15,16}

6 CONCLUSIONS

From a physician's point of view, in vivo relaxometry, at its present stage, is suited neither to characterize nor to type or grade diseases in the human body; it is possibly useful in the follow up of therapy, but other methods seem more feasible in clinical surroundings. From a scientist's point of view, relaxometry is a challenging area of research: (a) in vivo, to try monitoring therapy; (b) ex vivo or in vitro, to try to characterize tissues and to understand contrast behavior. The optimum method for the latter is field cycling relaxometry.

1 INTRODUCTION

1.1 Proton $1/T_1$ and $1/T_2$ Nuclear Magnetic Relaxation Dispersion Profiles of Mobile Water of Tissue

The clinical utility of magnetic resonance imaging (MRI) derives directly from the fact that $1/T_1$ and $1/T_2$ of the protons of (mobile) tissue water vary from one tissue to another.¹ This is true despite the important physiological fact that (with the notable exceptions of brain² and adipose tissue³) all soft tissues, and blood as well, contain close to 80% water; the remainder is predominantly protein. Gray matter of adult brain has a somewhat greater water content. Furthermore, as indicated by the linewidths and integrated intensities of the proton water signals, most, if not all, tissue water is highly mobile and not highly compartmentalized on an MRI timescale,^{4,5} the latter indicated by the observed rate of self-diffusion of tissue water, generally found to be within a factor 2 of that of pure water. This means that, in an image in which relative brightness is derived solely from the intrinsic magnitude of the proton signal, in turn proportional to the mean local density of tissue water (the protein proton lines are too broad to contribute to the signal), there will be little contrast between adjacent tissues, and MRI would be of limited clinical utility. Indeed, such a water-density map of the adult head would show gray matter brighter than white (contrary to what is often seen in clinical practice, in which many brain images are heavily T_1 -weighted) since the latter has ~10% of its water displaced by lipid-rich myelin, with protons that also have too broad a linewidth to contribute measurably to signal intensity; hence the importance of relaxation rates.

We first examine the phenomenology of water-proton relaxation in tissue and its models (solutions of immobilized protein), concentrating mainly on $1/T_1$ (rather than on $1/T_2$, which is much more difficult to measure) as a function of static magnetic field B_0 , for which most data are extant.⁶ Such a data set is termed a nuclear magnetic relaxation dispersion (NMRD) profile.⁷ The rather remarkable finding is that NMRD profiles of almost all tissues (excluding white matter and fat) have very nearly the same functional form,⁶ with a magnitude that varies little with temperature (less rapidly, for example, than does water viscosity). It is this magnitude, which increases with decreasing temperature, that is tissue-dependent but, unfortunately, not tissue-specific, due to the spread and overlap of amplitudes for different types of tissue. A noteworthy fact, only recently realized,^{8,9} is that the form of the NMRD profiles of tissue is indistinguishable from that of protein-water systems

in which the rotational mobility of the macromolecules is highly restricted. Examples are polymeric protein, including adult sickle deoxyhemoglobin¹⁰ and the fibers of collagen;¹¹ globular proteins cross-linked either by thermal denaturation⁵ or chemical linking;^{8,9,12,13} protein restricted by close packing,¹⁴⁻¹⁶ and highly hydrated protein powders.¹⁷ This correlation between the profiles of immobile protein and tissue is intriguing, particularly when it is realized that, to a first approximation, the tissues of concern are indeed mainly protein and water. An immediate inference is that the protein of tissue is itself rotationally immobile (unlike, for example, similar concentrations of hemoglobin in red cells).¹⁰ Accordingly, we speculate (at the end of the paper) how this may relate to both cell function and cell dysfunction since, in the last analysis, it is the molecular basis of relaxation that relates directly to the success of MRI in diagnostic medicine.

The mechanistic relation of the rates of solvent nuclear relaxation to the degree of immobilization of solute protein has only recently been clarified,⁸ and a quantitative molecular theory developed.⁹ Accordingly, after presenting the phenomenology of NMRD profiles of tissue and its protein models, and the implications of this phenomenology, we summarize the theory, first its qualitative aspects and then its quantitative molecular details. An important finding is that the dominant contributions to $1/T_1$ and $1/T_2$ of protein and tissue (which include the mechanisms that transfer magnetization between the solvent and solute Zeeman reservoirs) involve protein-water interfacial sites that cover but a small fraction of the traditional hydration monolayer,^{8,9} a point that was argued for solutions of mobile protein as early as 1969.⁷ For these all-important sites (accounting for only $\sim 4 \times 10^{-4}$ of the life history of a water molecule of tissue, and related to multiple hydrogen bonding^{8,9}), the interfacial interaction lifetime τ_M is $\sim 1 \mu\text{s}$; the remainder of the time water molecules are essentially as free and mobile as in pure water. For immobile protein, this relatively long τ_M becomes the correlation time for the relaxation processes that dominate all water relaxation in tissue. In addition, the relaxation mechanisms for the protein protons become characteristic of the solid state. This, together with these special interfacial sites, is the basis for the NMRD profiles of tissue and immobile protein. In addition, it is at these few sites that, to first order, *all* proton relaxation in tissue, water and protein, occurs.⁹

1.2 Relaxometry and Relaxometers

The fact that tissue water is essentially liquid means that motional narrowing mechanisms determine $1/T_1$ and $1/T_2$ of tissue water.^{18,19} It follows that relaxation rates depend on the applied field B_0 for nuclear Larmor frequencies $\geq 1/2\pi\tau_M$ which, for tissue and its model systems, means $\geq 0.1 \text{ MHz}$. A concomitant is that $1/T_1$ and $1/T_2$ should become equal (except in certain unusual cases) at lower values of B_0 . At typical imaging fields, which are higher ($\geq 20 \text{ MHz}$ proton Larmor frequency, or $\geq 0.5 \text{ T}$), both $1/T_1$ and $1/T_2$ have decreased substantially, with $1/T_1$ having the greater field dependence. Typically, $1/T_2 \approx 10/T_1$ for tissue water protons over much of the imaging range. Measurement of the dependence of relaxation rates on B_0 is one aspect of a broad research field (named 'Relaxometry' about a decade ago; by SHK) which also includes augmentation and application of theory and development of

instrumentation. In order to gain insight into mechanisms, relaxation rates must be measured over a wide range of B_0 that includes the major dispersive regimes of the NMRD profiles and, preferably, the temperature dependence of the profile itself. For the present purposes, this means measurements to fields as low as 0.01 MHz and as high into the imaging range as possible (the latter data are also useful for predicting MRI intensities, often convenient in their own right), and from 5 to 35 °C.

Measurements of NMRD profiles require specialized instrumentation not available commercially. Ours, called a 'field cycling²⁰ relaxometer' (FCR), has been refined and optimized for measurements of $1/T_1$ of both protons and deuterons of 'liquid' samples. (As a result, for example, contributions from broad solid state lines are not seen, nor can the fast component of biexponential decays readily be studied. Designs for solid state applications exist;²¹ the major trade-off is a much increased power requirement.) In the present applications, only mobile water contributes to the signal, typically ~90 M protons, quite unlike the mM protein-proton concentrations common in high-resolution NMR. Nonetheless, by the nature of field cycling, signal sensitivity varies as B_0^2 , and special procedures are needed to obtain good data at low fields. In addition, because the field must be switched, the signal is incoherent and signal averaging is not readily done; rather, adequate signal amplitude at lower fields is obtained by initially polarizing the proton spins in a high field (50 MHz presently), then switching the field rapidly [(at a rate of ~1 MHz (ms⁻¹))] to the value at which $1/T_1$ data are desired. Then the magnetization is allowed to decay toward its equilibrium value for a 'measure time,' and the resonant field is switched to 7.5 MHz in the present system, where a 90°–180°-echo sequence is used to measure the remaining magnetization. This cycling sequence is repeated for a number of measurement times within the interval $1.5T_1$, and several times at $7T_1$, to obtain the equilibrium magnetization at the measure field. These raw data are then fit to a single exponential to obtain $1/T_1$. For measurements of $1/T_1$ at fields above 25 MHz (greater than one-half the polarizing field), the increase in magnetization from zero polarization is monitored. In either case, the resonant frequency remains fixed, so that measurements at any field require but one radiofrequency (rf); no retuning is necessary over the entire range of B_0 , and the system can be readily automated. With appropriate rf coils, $1/T_1$ of protons can be measured within $\pm 1\%$ for sample volumes between 20 and 600 μL . To measure deuteron profiles, the resonant field is increased to produce a deuteron resonance at 7.5 MHz (~48 MHz for protons), and the rf pulse lengths adjusted appropriately.

Clones of our FCR, with improved circuitry based on the early ideas of Redfield et al.²⁰ and highly automated, both for data collection and analysis,²² have been installed in a small number of university laboratories in the US and Europe. However, the present article, essentially a monograph, is based on data taken by us in association with many visiting collaborators.

2 PROTON $1/T_1$ NMRD PROFILES OF TISSUE AND MODEL SYSTEMS

2.1 Tissue

Figure 1 shows profiles of three tissues from an adult male (accident victim):⁶ skeletal muscle, spleen, and lung. Data for a

Figure 1 Proton $1/T_1$ NMRD profiles⁶ of three normal human tissues, skeletal muscle (■), spleen (▼), and lung (●), and that of an astrocytoma (brain tumor, ▲), all near 36 °C. Also shown are expanded data, in the 1–4 MHz range, for rat heart (○), at 10 °C, the latter to illustrate spectral structure generally found in profiles of tissue (see text). The solid curve through the human muscle data is a smooth curve generated to match these data.²² The broken curves derive from the solid curve by scaling it vertically by a constant factor (with a small correction for the water background), indicating that all the profiles have the same functional form

resected astrocytoma (a common, highly variable, often aggressive brain tumor) are also shown. For a given normal adult tissue, there is little variation of $1/T_1$ profiles among individuals, whereas, for different tissues, the range of relaxation rates at a given B_0 is about a factor of 3 between the lowest magnitude profiles (gray matter) and the highest (liver and muscle). In contrast to normal tissue, astrocytomas have a comparably large range of $1/T_1$ for fixed protein content, and a comparably large (and uncorrelated) range of protein content as well.²³ How, and to what extent, this variability relates to neoplastic (cancerous) transformation of the native tissue that produces the astrocytoma is an open question at this writing.

Figure 1 also includes a limited portion²⁴ of the profile of rat heart (which is mostly muscle), on an expanded vertical scale, to illustrate peaks in $1/T_1$ that are seen in the 2–4 MHz region in most tissues, and are always present in immobilized protein model systems, but never in mobile systems. Taking sufficient data to characterize these peaks is very time-consuming so that there are few published studies of these spectral features.^{12,13,24–26}

The solid line, Figure 1, derives from a least-squares comparison of the muscle data with a nonintegral inverse power of B_0 , often a good representation of tissue-like NMRD profiles.²² The broken curves all derive from the solid curve by scaling it down by a different constant factor (first subtracting and then adding back the small water background rate of 0.3 s⁻¹). These impressive fits, to four tissues of widely different type and function, demonstrate the similarity of the NMRD profiles of

most tissues. This means that, at a given temperature, a single number characterizes the relative relaxation rates of any two given tissues, for all B_0 . A further implication is that tissue-specific details of either morphology or anatomical structure do not enter into the gross aspects of the NMRD profiles, perhaps not surprisingly since it has been previously noted that, on an MRI timescale, tissue water molecules diffuse sufficiently far so as to sample both the intra- and intercellular tissue environments; their protons thus report a grand average of the relaxation mechanisms present throughout the tissue.

It may well be that the structure and magnitude of the peaks is more tissue-dependent than the form of the underlying monotonic behavior of the typical tissue profile; this remains to be determined. At present, it is known that the origin of these peaks relates to the amino (NH) groups of the protein as sources and sinks of magnetization. The ^{14}N nuclei, with $S = 1$, differ in energy because of the interaction of their electric quadrupole moments with local electric field gradients, giving two excited levels about 2.2 and 2.8 MHz (proton Larmor frequency) above their ground states. There is rapid transfer of magnetic energy between these ^{14}N nuclei (which also have a small magnetic moment) and their NH protons (which are very close) when the proton Zeeman splitting matches possible transitions among the quadrupolar levels. These protons then become sinks for proton magnetization that diffuses by. Although the theory is difficult to quantify (since insufficient data exist regarding the ^{14}N relaxation parameters), the existence of such peaks in the $1/T_1$ profiles of mobile water indicates that there is extensive coupling of the water Zeeman reservoir with NH groups throughout the protein molecules. In support of the foregoing ideas, these peaks are replaced by the deuterium quadrupole splitting when the protein amino groups are deuterated.¹³

Figure 2 shows $1/T_1$ NMRD profiles of human gray and white matter from adult and neonatal brains.^{2,27} Here one sees a specific contribution from myelin, the water–cytoplasm–phospholipid ‘jelly-roll’ which surrounds the neuronal axons of adult, but not neonatal, white matter. This phospholipid is ~50% cholesterol. Again, the three broken curves have the same functional form, that of the curves in Figure 1. The relative magnitudes of the adult and neonatal gray matter can be accounted for by the known differences in water content.² The contribution of myelin (the difference between the white and gray matter profiles) has been ascribed to water molecules that hydrogen bond to the cholesterol molecules,²⁷ imbedded in myelin, at their hydrophilic hydroxyls; these cover much of the myelin surface. This binding, with residence times $\tau_M \sim 10^{-10}$ s, allows the protons of the bonded water molecules to interact with cholesterol protons in the lipid bilayer, itself rigidified by the cholesterol, thereby producing conditions not dissimilar to those of immobilized protein. Two major differences from protein–water interfaces are the much shorter value of τ_M for myelin lipid and its much larger density of surface sites for hydrogen bonding.

Adult white matter is one of the very few tissues for which the $1/T_1$ NMRD profile cannot be fit by the standard ‘immobile’ form. [Interestingly, adipose tissue (fat) has an NMRD profile very similar to the myelin contribution in adult white matter, Figure 2, but with a threefold greater magnitude.^{3,4,6}] That this profile includes a specific myelin contribution has also been argued from the temperature dependence of this pro-

Figure 2 Proton $1/T_1$ profiles of four samples of human brain,² adult white (○) and gray (●) matter, and neonatal white (□) and gray (■) matter, at 35 °C. The broken curves are scaled from the solid curve, Figure 1. The difference between these lower three profiles has been attributed to differences in water content.² The difference in functional form of adult white and gray matter has been attributed to cholesterol, a component of myelin lipid.^{2,27} Neonatal white matter is unmyelinated

file, which is anomalous.² In myelinated white matter, the water in direct interaction with cholesterol is ~15% of the total water and it must mix with the majority axonal water within a relaxation time to communicate its relaxation rate, which reflects the state of the myelin lipid, to the signal. This requires diffusive permeation by water of many layers of lipid and one might indeed think that the mixing rate would be too slow for the foregoing mechanism to account for the white–gray difference in adult matter, Figure 2. In fact, in humans, the mixing rate is adequately rapid at physiological temperature, but not at 5 °C; the putative myelin contribution, Figure 2, has been shown to disappear progressively as the temperature is lowered.² No such temperature anomaly is seen in the profiles of neonatal (unmyelinated) white matter.

Myelin is a complex lipid, containing phospholipids (such as sphingomyelin and galactocerebroside) with OH groups to which myelin water can hydrogen bond. Certainly, the $1/T_1$ component of white matter attributable to myelin is associated to a large degree with the presence of cholesterol which, as noted, rigidifies the lipid structure. This not only augments the contribution of hydrogen bonding to relaxation at cholesterol sites, but can also enhance the role these other lipids may play. Little, if any, of this has been sorted out at present, something that will have to be addressed if applications of quantitative MRI are to be made, for example, to the many diseases associated with breakdown of myelin (including multiple sclerosis).

2.2 Irreversible Immobilization of Albumins

The upper profiles of Figure 3(a) are the $1/T_1$ NMRD profiles of two *irreversible* albumin models for tissue: egg-white

immobilized by thermal denaturation,¹⁴ at 5 and 25 °C, and serum albumin immobilized by chemical¹² cross-linking. The lower profiles are those of the native albumins, before immobilization. The inflection frequencies of the latter, in the 1–2 MHz range, are known to relate to the rate of protein rotational Brownian motion.²⁸ This relationship has been apparent for almost 25 years,⁷ and has since been confirmed for globular proteins over a 1000-fold range of molecular weight.⁶ The upper three profiles show the changes brought on by immobilization, which alters the profiles in three major ways visible in Figure 3(a): the functional form changes; the dependence on temperature decreases; and structure appears in the 2–3 MHz range, as also seen in Figure 1 for heart muscle. Another change, not shown, is that the high-field $1/T_2$ increases dramatically. For mobile protein, the high-field value approaches 0.3 of the low-field value (consistent with the predictions of motional narrowing theory¹⁹) whereas, after cross-linking, the high-field $1/T_2$ becomes about equal to the 0.01 MHz value of $1/T_1$. This is also the case for tissue. And finally, a point that will be returned to, the rate of interchange of Zeeman energy between protein and water protons is enhanced at least 20-fold.^{29,30}

2.3 The Reversible First-Order Transition of Sick Hemoglobin

Figure 3(b) shows a sharp but *reversible* change in form of the NMRD profile from mobile to immobile,¹⁰ here due to the entropy-driven first-order phase transition of sickle deoxyhemoglobin from monomeric (or slightly oligomeric) protein at 6 °C to a polymeric gel at 25 °C. (The hemoglobin concentration was chosen to bring the transition temperature into a convenient range.) The profiles of sickle hemoglobin ($\square$) and adult normal hemoglobin at 6 °C (the latter not shown) are essentially the same. Were the fluid–gel transition not to occur, the near-Lorentzian sickle hemoglobin profile ($\square$) would change form, because of the variation of solvent viscosity, to that of the 25 °C profile of normal hemoglobin ($\circ$), shown here as a control. Instead, the form of the profile ($\blacksquare$) becomes indistinguishable from that of tissue, Figure 1. Thus, with sickle hemoglobin (because the transition is sharp, reversible,

Figure 3 (a) A comparison of the proton $1/T_1$ NMRD profiles of native (mobile, lower profiles) and irreversibly immobilized albumins (upper profiles), ~12 wt.% protein, at 5 (●) and 25 (□ ○) °C. One sample was bovine serum albumin (□),¹² chemically cross-linked using glutaraldehyde, and the other hen egg-white,¹⁴ native and cross-linked by thermal denaturation (○ ●). It is clear that immobilization alters the functional form of the profiles, reduces their temperature dependence, and introduces structure akin to that shown in Figure 1 for heart muscle. (b) The mobile–immobile distinction, here illustrated for the reversible first-order transition found in sickle hemoglobin¹⁰ (Hgbn S). The profile of sickle hemoglobin at 6 °C (□) is that of mobile protein, as in (a), and is the same as that of normal adult hemoglobin (not shown) at that temperature. Were the reversible polymerization associated with sickle hemoglobin not to occur, its profile would become that of normal adult hemoglobin (Hgbn A, ○) at 25 °C, the change being that of the viscosity of water. Instead, the profile becomes like those of the immobile albumins (a) and tissue, Figure 1. (c) The reversible mobile–immobile transition in a homogenate of calf eye-lens,¹⁴ here brought on by dilution of the homogenate (○ ●) 1:1 with buffer (□ ■). Data¹⁴ are shown for 5 (● ■) and 25 (○ □) °C

and both oxygen and concentration dependent) one can study the mobile-immobile change in profile by a slight alteration of temperature for a wide range of specimen conditions.

2.4 The Continuous Reversible Transition with Concentration of Eye-Lens Protein

Figure 3(c) shows another *reversible* mobile-immobile comparison,¹⁴ here a striking change that varies continuously with protein concentration (i.e., not abruptly with either temperature or concentration as for the first-order transition of sickle hemoglobin.) The initial sample (upper profiles) was from calf eye-lens homogenate at 5 °C (●) and 25 °C (○), which was then diluted 1:1 with buffer to obtain the lower profiles (■ □). The concentration-dependent transition is known to be dominated by the protein α -crystallin,¹⁴ the largest of three classes of crystallins; profiles of the purified protein behave similarly.¹⁵ α -Crystallin is a roughly spherical protein which, for reasons relating to lens transparency, is somewhat akin to a sponge: each molecule contains close to its own volume of water, making it twice the volume of most soluble proteins of comparable protein mass. As a result, and unlike most globular proteins, above ~15% solute by volume, intermolecular protein interactions significantly slow rotational motion. As an aside, similar effects are seen in many crystallins, mammalian and nonmammalian, and relate to the need to reduce the density fluctuations in lens, and thus in refractive index, so as to lower scattering and increase lens transparency. That this packing does enhance protein-protein interactions, important for NMRD profiles, is readily confirmed by the large colloidal osmotic virial coefficients for crystallins.^{31,32}

Nitrogen-14 peaks, at 2.2 and 2.8 MHz, are particularly clear in the upper two profiles, as is the small difference peak near 0.6 MHz, which is barely apparent in Figure 3(a). (The apparent greater width of the 0.6 MHz peak is an artifact of the logarithmic horizontal scale.) They are essentially gone at the 50% lower protein concentration, which emphasizes the highly nonlinear behavior of the mobile-immobile transition.

2.5 Summary and Implications of Phenomenology from Proton NMRD Profiles

The data so far demonstrate the universality of the form of the proton $1/T_1$ NMRD profiles found for tissue and systems of immobile protein. It is fair to say that, over four decades of B_0 , for a fixed protein content, the profiles are essentially indistinguishable. Indeed, from measurements of any relaxation parameter, $1/T_1$, $1/T_2$, $1/T_{1\rho}$, and cross relaxation, at any temperature and field, whether using a relaxometer or an imager, it is not possible to distinguish tissue from one of its immobile protein model systems. This is remarkable.

We have assumed throughout that water of tissue is highly mobile, and that its bulk properties are little influenced by most macromolecular structures, including membranes, a view supported by a large body of data. The rapid self-diffusion of water in most tissue means that, within a typical relaxation time (~0.1 s), a water molecule diffuses about 35 μm , i.e., about five or more cell radii. That water is not impeded significantly in averaging the intra- and extracellular environments in tissue within a relaxation time means that considering tissue water as free is

an excellent starting point for going beyond phenomenology to a molecular theory of relaxation in tissue. To the extent that some tissue-sensitive effects can be observed, which arise from a breakdown of these simplified views, for example at the boundary of two tissues, or that they can be magnified by experimental design, means that NMRD methods can be used to study the impediments to the motion of water that in reality do exist in tissue. This was already discussed here for myelin of white matter.² A second example is $1/T_1$ of blood. Here, the intracellular hemoglobin and the extracellular plasma proteins are mobile, and the $1/T_1$ profiles of blood are essentially the sum of these independent contributions, even though about one-third of the water is intracellular at physiological temperature; this confirms the rapid exchange rate of water across the red cell membranes.³³ However, at lower temperatures, particularly with a sufficient concentration of paramagnetic ions added to the plasma, the assumption of rapid averaging by the water molecules of the accessible environments becomes invalid; water exchange rates from cells have been measured by NMRD methods. Calculations for tissues, using these rates, reinforces the validity of assuming the high mobility and extensive diffusive range of water in tissue.

From the foregoing phenomenology, we can speak of tissue and solutions of immobilized protein interchangeably, and consider water in each as highly mobile. It is particularly convenient to do this, since rewarding studies can be carried out either on more dilute macromolecular systems or with partially deuterated solvent, something difficult (but not impossible¹²) to accomplish with tissue.

The arguments that water molecules of tissue diffuse as if in neat water, essentially that there is no long-range structure to tissue water, can be extended to estimate the time for permeation of membranes by water molecules from the 'dissolve-and-diffuse' model.³⁴ In this view, membranes (typically ~150 Å thick) are regarded as lipid solutions in which water molecules have very low solubilities but maintain their usual high mobility. Those few water molecules that penetrate the lipid diffuse across the membrane in a time determined by the diffusion constant of water in the neat bulk lipid, close to that for self-diffusion of water. The concept is that, except for minor effects of hydrogen bonding, diffusion of water through an array of (mostly) CH_2 moieties cannot be much different, mechanistically, from diffusion through an array of H_2O molecules; it is the low probability of a water molecule being in a hydrophobic lipid environment that dominates permeation. Using measured bulk solubilities of water in lipid accounts for the observed permeabilities quite well, considering the wide range of their values. One can then estimate this permeation time to be ~0.1 μs , sufficiently rapid to support the basic approach used here.

3 PROTON AND DEUTERON NMRD PROFILES IN MODEL SYSTEMS WITH DEUTERATED SOLVENT

3.1 Cross Relaxation, Magnetization Transfer, and Immobilization

In protein solution and in tissue, a given water proton can be relaxed by the proton on the same water molecule (both in

solution and when hydrating protein) and by protein protons. The first contribution is proportional to the probability that its neighbor is a proton; deuteration of solvent reduces this contribution proportionately. Its effect on relaxation rates arises from the influence of binding of water to protein on the overall molecular dynamics of solute waters, and is often called the 'hydrodynamic' contribution. The magnitude of this contribution can, in principle, be obtained by measuring solvent deuteron $1/T_1$ profiles, since intramolecular electric quadrupolar interactions dominate deuteron relaxation in water molecules; magnetic dipolar interactions with either solvent or solute protons are usually negligible. In practice, however, decreased signal intensity and an altered Larmor frequency range (associated with the sixfold lower g value of deuterons) makes measurements of deuteron NMRD profiles less informative. In addition, the ~30% contribution of proton–proton interactions between different water molecules in solution (a contribution that is not known precisely for protons and does not exist for deuterons) reduces the accuracy of the comparison of proton and deuteron results in the presence of protein, and hence the accuracy with which the proton hydrodynamic contribution can be obtained. Nonetheless, such comparisons have been invaluable in clarifying the nature of the proton $1/T_1$ NMRD profiles of immobilized protein.

The second contribution, from protein–water intermolecular proton interactions, is properly called³⁵ 'cross relaxation'. It is the totality of those interactions that determines the relaxation rates of water protons, which can be attributed to the presence of protons in solute protein (not simply because of the presence of solute). It includes 'magnetization transfer', the exchange of Zeeman energy between solute and solvent reservoirs without alteration of the *total* Zeeman energy; i.e., without exchange of energy with the lattice. This magnetization transfer arises from zero quantum spin flips when water molecules are bound at interfacial sites. It also includes the single and double quantum transitions that cause exchange of Zeeman energy between either (or both) Zeeman reservoir(s) with the thermal energy of the lattice. It is only these dissipative cross-relaxation transitions that determine, ultimately, the rate of interconversion of magnetic and thermal energy in the system. In reality, however, the observed $1/T_1$ is the slower of the biexponential decay; it *appears* to be influenced by magnetization transfer, as clarified below. Cross-relaxation effects, and their resolution into magnetization transfer and dissipative components, have recently been clarified by measurements of proton profiles in systems with partially deuterated solvent.⁹ Deuteration reduces the hydrodynamic contribution for protons, as well as the size of the solvent Zeeman reservoir, hence enhancing the importance of cross relaxation in two ways, as seen below.

3.2 Deuteron NMRD Profiles in Albumin Solutions

Figure 4 is the deuteron analog of Figure 3(a); it shows deuteron $1/T_1$ NMRD profiles of native and chemically cross-linked bovine serum albumin (BSA).⁸ The near-Lorentzian profile of the native protein is similar in form to the lower proton profile, Figure 3(a) (○), with comparable inflection frequency. Its magnitude is greater because the quadrupolar relaxation mechanism of deuterons leads to relaxation rates that are intrinsically about eightfold greater than analogous rates for protons, as judged from their comparative values of $1/T_1$ in

pure water (light and heavy) at 35 °C. What is grossly different is the deuteron profile of the cross-linked protein, here seen to be also near-Lorentzian, rather than tissue-like. Cross-linking has lowered the major inflection, which is now centered near 0.1 MHz. In addition, there is a second, smaller, contribution to $1/T_1$ at higher fields (under the tail of the major dispersion), with an inflection in the 2–4 MHz region. Its presence is emphasized by the expanded profile (●); there is a clear contribution to $1/T_1$ here that cannot be attributed to the tail of a Lorentzian dispersion centered near 0.1 MHz. (The immobile deuteron profile can be fit, within experimental error, by the sum of two Lorentzians,⁹ one centered at 0.1 MHz, the other at 4 MHz.) The major question, however, is what motion the 0.1 MHz inflection represents, since cross-linking inhibits protein rotation. The answer, discussed at length earlier,^{8,9} is that it is the lifetime of a class of water molecule bound at the protein–water interfaces; these dominate the hydrodynamic contribution to relaxation in immobile protein systems. It corresponds to $\tau_M \approx 1.0 \mu\text{s}$, which becomes the correlation time for the water–protein interaction. [The relation of inflection frequency^{6,7} ν to τ_M is $\tau_M \approx 1/(2\pi\sqrt{3}\nu) \approx 1/(11\nu)$.] From the magnitude of the profile, one readily computes the number of these sites, which is ~2 per protein molecule; this is out of about 700 water molecules that occupy the traditional first hydration layer of albumin. Refining things somewhat, one finds that there is a second class of water molecules, with $\tau_M \approx 23 \text{ ns}$, and a density of ~16 per protein molecule. The greater number of shorter-lived sites is offset by their much shorter τ_M , so that the net contribution to the low-field $1/T_1$ is about 25% of the total.

When the protein is mobile, the correlation time for the longer-lived sites becomes the rotational relaxation time of the protein, ~50 ns; the amplitude of the profile is reduced accordingly and the inflection shifted upward. For the 23 ns sites, their correlation time is shortened somewhat, but is still dominated by the faster exchange rate. The net result is a broadened dispersion, centered near 2 MHz, that is in reality the sum of two Lorentzians and which, in the past, was not appreciated; rather, a single, broader, Cole–Cole expression was used to catalog the data.^{5,28}

Historically, the deuteron data, Figure 4, are the more recent, whereas major insights into understanding the mobile–immobile transition in the NMRD profiles of protons came somewhat earlier.⁶ However, didactically, the data (Figure 4) present the clearest arguments for the global views being developed here to explain proton $1/T_1$ NMRD profiles of tissue and, by extension, contrast in MRI. So far, four parameters are sufficient to describe the *deuteron* $1/T_1$ NMRD profiles of both mobile and immobile protein systems: the surface densities of two classes of water binding sites (about 2 and 16 for the area of an albumin molecule) and the lifetimes (τ_M values) of water molecules in these sites (1 μs and 23 ns respectively). The mobile–immobile transition of Figure 4, as noted, is then explained by a lengthening of the correlation time for relaxation of a deuteron upon immobilization, mainly at the 1 μs site (for albumin).

3.3 Proton NMRD Profiles in Albumin Solutions

Figure 5 shows proton $1/T_1$ profiles for 9 wt.% cross-linked BSA⁹ in undeuterated (▲) and 90% deuterated (▼) solvent, at

Figure 4 Deuteron $1/T_1$ NMRD profiles for mobile (∇) and glutaraldehyde cross-linked bovine serum albumin⁸ ($\circ$), ~10 wt.%, at 35 °C. The solvent water is 46% protonated. (Deuteron profiles do not change with solvent isotopic composition.³⁵) The solid curves derive from a fit to the Cole–Cole expression. The major dispersion in the profile for the immobile protein is clear; another, smaller, contribution to $1/T_1$, with a dispersion in the 2–4 MHz region is readily seen when the data are expanded vertically threefold ($\bullet$)

Figure 5 Proton $1/T_1$ profiles of cross-linked bovine serum albumin,⁹ 9 wt.%, in 100% ($\blacktriangle$) and 10% ($\blacktriangledown$) protonated water solution, at 20 °C. The two solid curves derive from the theory of two interacting Zeeman reservoirs, as outlined here, with two classes of solute–solvent interfacial water binding sites. One class has two sites per macromolecule with a lifetime $\tau_M = 1 \mu\text{s}$, and a protein proton–water proton interaction equal to the intraproton interaction in water; the second class has 16 water molecules per macromolecule, $\tau_M = 23 \text{ ns}$, and a solute–solvent interaction four times greater. The two values of τ_M are associated with the dispersions near 0.1 and 4 MHz. The field dependence of the profiles below ~0.03 MHz is related to a mechanism³⁶ not considered here at all

20 °C. Despite the monotonic, tissue-like, dispersion of the data for the undeuterated sample (upper curve), it is clear from the profile for the sample with deuterated solvent (in which the role of cross relaxation is enhanced) that the situation is more complex: two distinct dispersive regions are clearly seen. This, and the fact that the amplitude of the profile for the sample with deuterated solvent is not 10% of that of the upper profile (as it would be if hydrodynamic interactions dominated relaxation), can only be explained in terms of cross relaxation. Moreover, if a global view of relaxation in these systems is to be had, it can involve no more than two additional parameters to explain the proton data in terms of the deuteron results (Figure 4): the cross relaxation rates at each of the two classes of sites. The two solid curves derive from a recent theory that does just this.

4 THEORY

4.1 A Qualitative Picture

The following is a sketch of a theory of interfacial relaxation that readily accounts for, *quantitatively*, all the data in the Figures, and more. We assert that the mobile–immobile transition relates to a transition from liquid to solid state relaxation for protein protons.⁹ The main criterion for such a transition is that the precession rate of these protons in the local field generated by their neighbors becomes comparable to the rate of Brownian rotation of the protein (sometimes called the Redfield criterion). The division is at a molecular weight of ~50 000 kDa. For slower rotation, protein protons relax as in a solid; to first order, nondissipative spin diffusion is rapid, with jump times (T_2) ~ 13 μs , so that magnetization spreads rapidly and without loss since, again to first order, there are no dissipative (T_1) processes except at specialized sites. The latter include the protons of all the protein NH groups, which cross relax rapidly with ^{14}N nuclei when electric quadrupole splittings match proton Zeeman transitions, and the particular 1 μs interfacial sites being discussed. (The contribution of rotationally mobile protein methyl groups, often discussed for high-resolution NMR at high fields, is minor at the fields considered here.⁹)

For albumins (as illustrated here), and for lysozyme,¹³ myoglobin (unpublished), carbonic anhydrase,⁸ hemoglobin,¹⁰ α -crystallin¹⁵ and, by inference, most of the proteins of tissue, there are sites at the protein–water interface for which the water lifetime τ_M is close to 1 μs . The density of these sites is low, covering $\leq 1\%$ of the surface area, corresponding to only 2 (on average) for albumins (64 kDa), and, despite the fluctuations in number that might be expected, the surface density is found to be relatively constant among the proteins measured. (For cross-linked lysozyme, the profile is that of tissue, with a magnitude in keeping with that of other proteins. However, for crystalline lysozyme,³⁷ with water content comparable to that of cross-linked material, the profiles are quite different; a satisfactory explanation is that the ostensible, single, 1 μs site of lysozyme is at the point of intermolecular contact in the crystalline form studied. However, for the still smaller trypsin inhibitor studied by multidimensional NMR at 600 MHz,³⁸ and for which the correlation time for coupling of protein and water protons is not longer than ~100 ps, it would appear that there are no long-lived interfacial sites of the sort important in larger

proteins and in tissue.) Fluctuations in the average number density of these sites, however, could be large enough to account for the range of relaxation among different tissues, a point not yet established.

It was conjectured,^{9,29} and argued from water molecules found in neutron scattering studies of myoglobin crystals,³⁹ that such long-lived water molecules are each bound by four hydrogen bonds. The view was that each proton of a bound water molecule is held symmetrically between two hydrogen acceptors as, for example, the two oxygen atoms of a surface carboxylate, both deprotonated at physiological pH values. For myoglobin, one long-lived water proton was found shared between the nitrogen atoms of two surface histidines (B. P. Schoenborn, personal communication), in accord with the conjecture. For immobilized protein, τ_M becomes the correlation time for interfacial proton–proton interactions. For mobile proteins, this time is sufficiently long for the bound waters to sense the Brownian rotation of proteins lighter than ~3000 kDa.

For the 23 ns sites, corresponding to the higher field dispersion centered near 4 MHz, Figure 4, it was suggested that the waters are held by three hydrogen bonds.⁹ Their surface density, about 10 times that of the 1 μ s sites, as already noted, is not enough to make up for the shorter lifetime, so that their contribution to the NMRD profiles of immobile samples is relatively small.

It is implicit in the foregoing that the NMRD profiles derive from exchange of interfacial water molecules and not individual protons. This point was addressed very early on;⁷ the major qualitative arguments against proton exchange being important in the systems considered here are the insensitivity of NMRD profiles (a) to pH over the range 4–8 and (b) to buffer concentration.⁹ Quantitative arguments⁷ show that τ_M values for proton exchange near neutral pH, in unbuffered solutions, are longer than ~100 μ s, too long to be important here. The quantitative theory, based on water exchange, follows.

4.2 A Quantitative Molecular Formulation

Here we present an outline of the interaction of two Zeeman reservoirs in contact at a common interface, in terms of specific sites for their interaction.⁹ It is assumed that each reservoir can be characterized by a spatially uniform, time-dependent magnetization. Solvent uniformity is established rapidly by chemical self-diffusion, whereas solute uniformity depends on ‘spin-diffusion’ which, when effective (as it is in immobile protein), is not a true diffusion but a lossless quantum mechanical spreading of a wave packet of magnetization. For mobile protein, in which spin diffusion is of limited range (~5 Å), the net effect is to reduce the apparent size of the protein Zeeman reservoir as seen by solvent protons; the theory is then applicable to both mobile and immobile systems. We consider only longitudinal relaxation; the analogous theory for transverse relaxation has been given.⁹

Let δS and δP be the fractional deviations from thermal equilibrium of the magnetizations (or total magnetic moments) of the solvent and solute Zeeman reservoirs respectively, and let m (generally >1) be the ratio of solvent to solute total equilibrium Zeeman energy. (m is *not* the ratio of two magnetizations, each of which is a volume density of magnetic

moment and similar for solvent and solute protons.) As an aside, if the Zeeman reservoirs are both of the same spin species, such as protons, then m is the ratio of the total number of protons in each. On the other hand, if the two reservoirs are of different species, e.g., electrons and protons, then m is the ratio of total number multiplied by the ratio of g values, including sign. This has implications for magnetization transfer by the Overhauser effect,⁴⁰ not considered here, except to note that the difference in sign of the electron and proton g values makes m negative and can make the signal *larger* when the ‘protein reservoir’, now the electron system, is saturated.

δS and δP span the range ± 1 , with -1 corresponding to infinite temperature, i.e., saturation. The solvent NMR signal is relatively narrow (typical of a liquid) whereas that of the macromolecular solute (whether mobile or immobile) is broad; thus the signals in NMRD and MRI of tissue and model systems can be taken to be those of solvent. Conveniently, the width of the solute levels allows one to manipulate the magnetization of the solute spins, independently of solvent, by rf irradiation off-resonance from the solvent line but within the solute proton linewidth.

The most general description of the time dependences of δS and δP is given by two linear, coupled, differential equations,

$$\begin{aligned} d(\delta S)/dt &= -\lambda_S(\delta S) - \sigma_S(\delta P) \\ d(\delta P)/dt &= -m\sigma_S(\delta S) - \lambda_P(\delta P) \end{aligned} \quad (1)$$

where the major assumption is that the influence of one reservoir on the other is linearly proportional to the difference in their spin temperatures. (The factor m in the second equation is dictated by the principle of detailed balance.) As a result of linearity, the effect can be expressed, as in equation (1), in terms of the individual deviations of each reservoir from its own equilibrium magnetization. We note, even before defining the coefficients λ_S , σ_S , and λ_P in equation (1), that a consequence is to introduce the interactions that couple protein and solvent into both the diagonal and off-diagonal coefficients, equation (1) (see below).

The most general solution of the two equations is that both δS and δP vary in time as the sums of (the same) two exponential decays of the form $\exp(-\lambda t)$, with the two eigenvalues for λ satisfying the quadratic equation

$$\lambda_{\pm} = ((\lambda_P + \lambda_S) \pm \{[(\lambda_P - \lambda_S)^2 + 4m\sigma_S^2]^{1/2}\})/2 \quad (2)$$

It is readily shown that both roots are positive, so that magnetization always approaches an equilibrium or steady state limit; it may decay or grow in time, but it never diverges exponentially. In most experiments, it is λ_- , the slower rate, that is actually measured and reported as $1/T_1$ (by us and others, in relaxometry and MRI).

Before relating the coefficients in the differential equations to molecular mechanisms (which is the major problem to solve, and which has only recently been accomplished⁹), we consider cross relaxation and magnetization transfer. From the first expression of equation (1), if δP can be maintained constant in time, by whatever means, then the time course of δS becomes a single exponential with rate constant λ_S . This is the situation in the many current reports of MRI-related experiments, loosely referred to as ‘magnetization-transfer contrast’ (MTC).^{41–43} Off-resonance irradiation is used to saturate the

solute magnetization, i.e., force $\delta P = -1$. (This is not as straightforward as it may seem, since the solvent line, though narrow, is near-Lorentzian, and thus has long tails, whereas the solute line is Gaussian; it can be difficult to achieve $\delta P = -1$ by off-resonance irradiation without putting unwanted energy into the solvent line.⁴⁴)

In a typical MRI-MTC experiment, in which only the signal intensity due to δS is measured, its magnitude is unity without irradiation (since $\delta S \rightarrow 0$ at long times), whereas it approaches σ_S/λ_S for saturating irradiation [from the first of equation (1), provided that m is positive], thus reducing the range of signal swing when σ_S is negative, as it is at imaging fields [as seen in equation (3) below]. Since the time constant at saturation gives λ_S , one can obtain the off-diagonal ‘transfer’ term from the change in signal amplitude when the off-resonance rf field is applied.

As already noted, for a proton of a water molecule bound to protein, its magnetic dipolar interaction with a neighboring proton, either on the same water molecule or within the protein, can be described completely in terms of three transition probabilities, w_0 , w_1 , and w_2 , respectively the zero, single, and double quantum transition rates. The first is a mutual spin flip, with both spins always aligned antiparallel, and involving no energy exchange with the lattice; the second is a single flip with Zeeman–lattice exchange; and the third a double flip of parallel spins, again with energy exchange with the lattice. In terms of microscopic interactions, we can define

$$\begin{aligned}\rho_S &= f_S(w_0 + 2w_1 + w_2) \\ \sigma_S &= f_S(w_2 - w_0)\end{aligned}\quad (3)$$

where

$$\begin{aligned}w_0 &= 0.1R_T\tau_c \\ w_1 &= 0.15R_T\tau_c/[1 + (\omega\tau_c)^2] \\ w_2 &= 0.6R_T\tau_c/[1 + (2\omega\tau_c)^2]\end{aligned}\quad (4)$$

Here ω is the proton angular Larmor frequency and R_T is a constant that characterizes the magnitude of the proton–proton magnetic dipolar interaction; for protons of water, $R_T \approx 7 \times 10^{10} \text{ s}^{-2}$. f_S ($\ll 1$) is the fraction of the solvent molecules bound at a particular class of site. Then, as we have shown,⁹

$$\lambda_S = R_S + \rho_S, \quad \lambda_P = R_P + m\rho_S \quad (5)$$

R_S includes the background rate of buffer (which may contain paramagnetic contrast-enhancing agents). R_P is $1/T_1$ of the protein protons in the absence of interactions with solvent. R_{SH} , the hydrodynamic contribution from interfacial interactions, is given by

$$R_{SH} = 2f_S(w_1 + w_2) \quad (6)$$

for undeuterated solvent, with R_T , equation (4), that of water. It is implicitly to be understood that there is a different f_S , R_T , and τ_c for each class of interfacial site; that the intramolecular transition rates must be reduced appropriately as solvent is deuterated; and that the w_0 , w_1 , and w_2 values that enter equation (3) are sums over all classes of sites. For immobile systems, τ_c is equal to the τ_M of any particular site.

The w_0 value, the only transition rate that is not a function of B_0 , is the measure of the rate of those mutual spin-flip transitions that transfer magnetization between Zeeman levels without exchange of energy with the lattice. The w_1 transitions catalyze solvent relaxation by inducing exchange of one quantum of Larmor energy between the Zeeman reservoir and lattice, giving cross relaxation but no magnetization transfer. Finally, w_2 causes double spin flips of parallel spins, with a net interchange of two Larmor quanta between Zeeman reservoirs and lattice, again producing cross relaxation with no magnetization transfer. As has been discussed above, for systems of immobilized protein and, by extension, tissue, w_1 and w_2 at the $1 \mu\text{s}$ sites are the major mechanisms for relaxation of solute and solvent protons at all fields below $\sim 2 \text{ T}$. At particular level-crossing fields, the totality of NH groups gives a $1/T_1$ contribution comparable to these few interfacial sites. At high fields, to $\sim 5 \text{ T}$, relaxation by mobile methyls dominates proton $1/T_1$, for *all* the protons present, until, at higher fields, this too disperses.⁹

For immobile systems, at high fields, defined such that $\omega\tau_M \gg 1$, $-\sigma_S = \rho_S = K$ as used in considerations of magnetization transfer contrast. It is interesting to note, from equation (3), that there can be a value of field at which σ_S goes through zero and changes sign. The sign is not important since σ_S enters quadratically in equation (2). However, when $\sigma_S = 0$, δS is uncoupled from δP [equation (1)], magnetization transfer contrast effects vanish, the hydrodynamic and cross-relaxation contributions to $1/T_1$ (at that field) become additive, and both can be obtained by comparing $1/T_1$ for protons and deuterons, or for protons as a function of solvent composition.

5 DATA AND THEORY

5.1 Proton NMRD Profiles of Immobilized Albumin in Deuterated Solvent

The solid curves in Figure 5 depend on six parameters:⁹ the surface densities of two classes of long-lived interfacial water binding sites, the respective water lifetimes, and the extent of cross relaxation at each class of site. The first four parameters were derived from, and therefore account for, the two deuteron profiles, (Figure 4). One need only shorten the correlation times for the hydrodynamic interactions, equation (2), to take account of the rotation of the native material, to go from the upper profile to the lower. In addition, by changing the value of R_T , equation (4), from that of deuterons to that of protons, still ignoring cross relaxation, one can account for the native proton profiles, Figure 3(a)⁹ (since, as already noted, the effective size of the solute Zeeman reservoir is much reduced for mobile protein). Two more parameters, the extent of cross relaxation of protons at each class of site for immobilized protein, give the two solid curves in Figure 5. The appropriate values of m are also required, here computed from the amino acid composition of the protein and the isotopic composition of the solvent. Three major features of the data are immediately accounted for: the dispersions near 0.1 and 4 MHz, and the comparable amplitudes of the two profiles (recall that one should be tenfold greater than the other in the absence of cross relaxation).

We submit that the essential nature of the proton $1/T_1$ NMRD profiles are explained quite well by the foregoing theory, par-

ticularly in view of the following two approximations. First, as B_0 is decreased below 0.03 MHz, the two Zeeman levels of the protein protons, which are quite broad in the solid state (essentially the width found for the excitation of MTC effects in MRI), begin to overlap. The result is a loss of quantization along the field direction in $\sim 13 \mu\text{s}$, essentially introducing a very effective T_1 mechanism into the protein where none existed before.³⁶ In the present work, this effect has not been considered, either for the protein protons or those of the bound waters. Thus, the comparison of data and theory below 0.03 MHz is expected to be poor. Second, all the data (for protons and deuterons in mobile and immobilized systems) are fit with six parameters associated with less than 3% of the traditional hydration layer: two classes of sites, with all the waters within each class taken as identical. These are rather gross simplifications.

5.2 Predictions of Theory

5.2.1 $1/T_{1\rho}$

There are several experimental findings that may not obviously relate to the ideas outlined here, but that are readily explained by the foregoing, and difficult to explain otherwise. One example is $1/T_{1\rho}$, in which $1/T_2$ of tissue (at relatively high values of B_0) is measured as a function of the amplitude of the rf resonance field B_1 . A dependence of $1/T_2$ on B_1 (by definition, $1/T_{1\rho}$) is found.^{36,45} Traditionally, such a dependence is attributed to the correlation time of fluctuations that induce relaxation. However, the reality is that, at large B_0 , when the Zeeman levels in the immobile material are well separated, the levels in the transverse plane, parallel and orthogonal to B_1 in the rotating frame, overlap unless B_1 is sufficiently large to remove this degeneracy. The dependence of $1/T_2$ on B_1 at high B_0 , then, should mimic the dependence of $1/T_1$ at low B_0 . The prediction has been verified;³⁶ both dispersions reflect the solid state linewidth of the protein proton Zeeman levels, and not a correlation time.

5.2.2 MTC Experiments in Solutions of Mobile Protein

If there is essentially no propagation of Zeeman energy from a protein–water interface to deep within the protein (essentially, because magnetization relaxes as it diffuses⁶) unless the protein is immobile, the net effect is to make the protein Zeeman reservoir very small from the viewpoint of a solvent proton. The major prediction is that magnetization transfer effects will be small in mobile systems. This has been shown for irreversibly immobilized albumin,²⁹ for the reversible ‘crowding’ transition for α -crystallin,³⁰ and even for whole blood,⁴³ for which the $1/T_1$ profiles are like those of mobile protein, and unlike those of tissue.

A particularly striking example of the linking of two relatively disparate physical observations is shown in Figure 6. Here, the magnitude of the magnetization transfer coefficient K , the high-field limit of $-\sigma_S$, measured in α -crystallin at 200 MHz in an MRI environment,³⁰ and the height of the 2.8 MHz peak [Figure 3(c)], obtained using a relaxometer,¹⁵ are plotted against crystallin concentration. The vertical scales were adjusted so that the data overlap, and the solid curve is chosen empirically to emphasize the similarity of the concentration dependences of these two variables. Recall that K is a measure of the rate of (dissipationless) magnetization transfer across the

protein–water interface, obtained by driving the protein proton spin temperature to infinity by saturation with off-resonance irradiation. These spins are tightly coupled to the radiation, and their relaxation rate within the protein is irrelevant. On the other hand, the ^{14}N peaks are obtained at low fields, and are a measure of the dissipation of solvent Zeeman energy caused by magnetization transfer across the interface, coupled with spin diffusion to NH moieties deep within the protein. The rather remarkable correlation between the two phenomena, both of which are easily linked only by the theoretical ideas elaborated here, is perhaps the best demonstration of their intrinsic validity.

5.2.3 The Equivalence of MTC and T_2 -Weighted Images

Most MRI protocols tend to rely on images constructed in the main from T_2 values of tissue since, as noted earlier, $T_2 \sim 0.1T_1$ in the MRI range, and a clinically useful image can be obtained in a shorter time than one that is T_1 -weighted. A second reason is that, as MRI moves to progressively higher fields, the observed $1/T_1$ values tend to disperse toward the water background rate, and distinctions among different tissues tend to disappear, whereas (as already noted) $1/T_2$ at high fields is comparable to $1/T_1$ at ~ 0.01 MHz. Thus the two types of weighting provide very different image contrast. (It is mainly for brain that T_1 -weighting is used, since this shows the gray–white matter distinction far better than does T_2 -weighting.²)

From the arguments that water of tissue is highly mobile, the ideas of motional narrowing apply, and $1/T_1$ and $1/T_2$ become equal in the limit of low B_0 , and are nearly so at 0.01 MHz. Since it has now been established that cross relaxation dominates $1/T_1$ at low fields, then it must dominate $1/T_2$ at both low and high fields. The contribution of cross relaxation to $1/T_2$ of tissue has not as yet been demonstrated directly, since MTC protocols are all modifications of pulse sequences for measuring $1/T_1$. Nonetheless, it is the general observation in the MTC–MRI community that MTC images are very much

Figure 6 Variation with protein concentration of K^{28} at 200 MHz and 19 °C (●) and of the magnitude of the 2.8 MHz peak¹⁵ at 25 °C (■), measured for α -crystallin. The vertical scales have been adjusted so that the data overlap and the smooth, solid curve (linear plus cubic terms) is drawn to indicate the similarity in the dependences of both parameters on protein concentration

like the analogous T_2 -weighted ones. From the argument above, following from the validity of motional narrowing, this is expected: $1/T_2$ at high fields is like $1/T_1$ at low fields, as regards cross relaxation. Thus, an MTC image, which by definition is an image of the spatial dependence of cross relaxation (which at high fields is dominated by magnetization transfer), should look like a T_2 -weighted image. It only remains to point out why magnetization transfer does not contribute significantly to $1/T_1$ of tissue at imaging fields, which requires a description of the biexponential decay modes of the two Zeeman reservoirs, protein and water, at imaging fields.

The two eigenvalues of equation (2) are associated with two decay modes which, because the transition probabilities w_1 and w_2 are field dependent, change character with field. At imaging fields, $w_0 \gg w_1, w_2$, which means that in the regime where cross relaxation is essentially all magnetization transfer, the eigenmodes become particularly simple: one is the very rapid mixing of the two Zeeman reservoirs, with $\lambda_+ = mK$, and the other an overall relaxation of the two coupled systems, at a rate determined by whatever relaxation mechanisms remain nondispersed. In this limit of rapid equilibrium between the two reservoirs, the actual rate of mixing (i.e., K) does not influence the slower $1/T_1$; both reservoirs relax toward ambient temperature together, slowly. However, if off-resonance irradiation is used to bring the protein Zeeman reservoir to infinite spin temperature, then the net relaxation rate is a balance between the rate K at which magnetization crosses the interface and the intrinsic $1/T_1$ in the absence of this irradiation; clearly the resulting $1/T_1$ is a function of K . Interestingly, the range of K among various tissues is about a factor 5, which is greater than the threefold range of $1/T_1$ or $1/T_2$ values, a reason that MTC contrast is, at present, being investigated rather intensively in many quarters. Nonetheless, few clear clinical applications have appeared as yet.

5.2.4 The Other 97% of the Hydration Layer

Extending the idea that one fewer hydrogen bond holding an interfacial water means an approximately 45-fold decrease in τ_M , corresponding to a correlation frequency of ~ 200 MHz for binding by two bonds, were all the waters this well bound, their $1/T_1$ would be ~ 350 -fold greater because of the density of sites, and (45^2) -fold less because of the shortened τ_M , for a net value of 0.15 of the low-field contribution to $1/T_1$ of the 1 μ s sites. For the data of Figure 1, this means high field rates (after solvent correction) threefold greater than observed. This is consistent with conclusions from earlier thinking that, although some dispersion in the 200 MHz region is observed⁷ (for mobile protein, for which the same arguments hold at high fields), no more than about one-third of the water molecules could have this two-bond lifetime of $\sim 4 \times 10^{-10}$ s⁻¹, which are those ostensibly associated with polar surface groups.⁴⁶ The remainder, the majority, must be even shorter lived.

6 CYTOPLASMIC ORDERING AND CYTOPLASMIC CHAOS

The major question posed by the foregoing is: why is a solution of immobilized protein such a good model for the magnetic relaxation of the water protons of tissue? As already

stressed, whether studied by relaxometry or by MRI, a sample of tissue cannot be distinguished by any measurement from a sample of immobile protein, a remarkable fact that indicates that the majority of protein in normal tissue is immobile, i.e., rotationally restricted. This is the more remarkable since there is not nearly sufficient lipid in tissue to form membranes that interact with all tissue protein molecules independently, a point not often realized. Yet there is significant cross relaxation observed only in tissue and immobilized protein, not in mobile protein solutions²⁹ nor in blood,⁴³ with its red cells that have no nuclei and little function other than to transport hemoglobin, and in which the hemoglobin is known to be mobile.¹⁰

We may conjecture that protein in normally functioning cells is organized into separate functional groups; e.g., those enzymes and structural proteins needed for a sequence of successive reactions that relate to a single complex biochemical function (such as electron transport) are held together, in specific relative spatial relationships, by interprotein and lipid-protein interactions that have developed over time in response to evolutionary pressures. These groups of protein may well be pinned to lipid at several points, but the general result, from geometric arguments, must be three-dimensional in its spatial organization, with a net inhibition of rotational mobility such that motion is slower than that of a mobile protein of 50 000 kDa. Another method of organization may involve controlled unfolding of protein, with the backbone threading through a membrane, conceivably more than once. Heat shock proteins and chaperonins may be examples. Whatever the mechanism, from NMRD observations, a majority of the protein of most tissue must be so organized to account for the magnitudes of the many profiles measured.

In addition, to account for recent results on abnormal cells,²³ an argument can be made that, again for reasons of cellular efficiency, the overall organization is such that groups of protein associated with disparate functions might well be arranged to interact minimally with each other so as not to impede their different functionalities.

Two points follow from this picture of functional organization of cytoplasmic protein, both of clinical relevance. The first is a conjecture regarding the effect of neoplastic (cancerous) transformation, in which normal cell functions become progressively more disrupted the more aggressive the tumor-type. One could imagine that, as an initial change, the delicate balance of protein interactions (those that cause proteins related to a particular function to group and those that keep separate groups apart) would be compromised. The net result would be 'cytoplasmic chaos', in which disparate groups of proteins begin to crowd each other with a net *loss* of the rotational mobility that remains. (Recall that, at the concentrations of protein in tissue, rotational mobility is a sensitive function of interprotein interactions.⁴⁶) This disorder, introduced by dysfunction, should increase cross relaxation, relative to some carefully normalized value related to the cell's macromolecular content. However, many changes are occurring in these circumstances so that it is difficult to do this normalization accurately. Nonetheless, recent studies²³ of astrocytomas (brain tumors arising from transformed astrocytes, which can range from relatively benign to very aggressive) indicate that these ideas of cytoplasmic chaos may be realistic: as the tumor cells become more primitive, the cell protein appears more immobile in NMRD profiles.

A second inference from the ideas of cytoplasmic organization and cytoplasmic chaos relates to tissues more complex than those considered here, such as joints. These structures are composites of a range of macromolecules, including collagen-containing cartilage. Here, the integrity of the collagen polymer is essential for normal functioning of joints. There is no question that magnetization transfer in collagen solutions is sensitive to structure, and there is the possibility that preclinical disease, e.g., arthritis, may manifest itself by changes in magnetization transfer arising from subtle alterations in the spatial organization of polymeric proteins in joints and their interaction with other cellular macromolecules, as evidenced in both the monotonic and structured regions of the proton $1/T_1$ NMRD profiles of resected tissue, of model systems, and, ultimately, in MRI.

7 PERSPECTIVES

Much progress has been made in understanding the relaxometry of tissue, motivated by the desire to understand, at the molecular level, the basis of contrast between tissues in MRI. It is fair to remark that the essence of longitudinal and transverse relaxation of water protons in tissue can now be accounted for: it is the protein of tissue, immobilized by interactions and structures yet to be further explored, which gives the NMRD profiles their characteristic form. Magnetization transfer and $1/T_{1\rho}$ are also accounted for. This should not only impact diagnostic clinical imaging, but also be of use in prognosis and monitoring therapy. Much remains to be explored: examples of diamagnetic systems are adipose tissue (important in breast cancer^{3,6}) and brain tumors that contain calcified deposits (which behave anomalously in MRI and relaxometry²³). In addition, there are open problems, not discussed here at all, that involve the natural paramagnetism associated with iron in the body: examples here are the iron storage protein ferritin and the evolving biochemical events following hemorrhage. Finally, there are questions that relate to potential pharmaceuticals which could compete with water at the relatively small total number of water binding sites in the body that make MRI useful in clinical medicine, thereby dramatically altering MRI contrast. Little of this was envisioned 50 years ago, at the genesis of NMR in the solid and liquid states.

1 INTRODUCTION

Radiofrequency (rf) radiation is defined as nonionizing electromagnetic radiation in the frequency range of 0–3000 GHz, as distinguished from the very high photon energies and frequencies associated with ionizing electromagnetic radiation (e.g., γ and X-rays).^{1–4} The rf spectrum includes radar, UHF and VHF television, AM and FM radio, and microwave communication frequencies.

Various research studies conducted over the past 30 years have reported that exposure to rf radiation may produce a variety of physiological effects including alterations in visual, auditory, endocrine, neural, cardiovascular, immune, reproductive, and developmental function.^{1–4} These biological changes were generally felt to occur due to rf radiation-induced heating of tissues.^{1–10}

Exposure to rf radiation may also cause athermal, field-specific alterations in biological systems that are produced without a significant elevation in temperature.^{1,4,5,11} The athermal bioeffects of radiation are somewhat controversial due to assertions concerning the role of electromagnetic fields in causing cancer as well as developmental abnormalities, along with the concomitant ramifications of such effects.^{1,4,5,8,11} A report from the United States Environmental Protection Agency indicated that the existing evidence on

this issue is sufficient to demonstrate a relationship between chronic exposures to low level, electromagnetic fields and cancer.⁸ However, the mechanism(s) responsible for such effects have yet to be defined. Therefore, there is an on-going effort to determine if there is any association between exposure to athermal levels of rf radiation and the abnormalities described above.

To date, no research has been performed to investigate the potential athermal bioeffects of rf radiation associated specifically with MR procedures. Those interested in thorough discussions of this topic are referred to the extensive review articles written by Adey⁵ and Beers.¹¹

During MR procedures, the majority of the rf power transmitted for imaging or spectroscopy is transformed into heat within the patient's tissue as a result of resistive losses.^{12–22} Not surprisingly, the primary bioeffects associated with the rf radiation used for MR procedures are directly related to the thermogenic qualities of this electromagnetic field.^{12–22} Therefore, this article will specifically discuss this aspect of rf radiation and its implications for individuals undergoing MR imaging or spectroscopy.

Prior to 1985, there were no published reports concerning the thermal and other physiological responses of human subjects exposed to rf radiation during MR procedures. In fact, there has been a general lack of quantitative data on thermal responses of human subjects exposed to rf radiation from any source. The previous investigations performed on this topic examined therapeutic applications of diathermy or thermal sensations related to exposure to rf radiation.^{1,3,4,23,24} These studies typically involved exposures to rf energy that were localized to small regions of the body.

Although there have been many investigations performed using laboratory animals to determine thermoregulatory reactions to tissue heating associated with exposure to rf radiation, these experiments do not directly apply to the conditions that occur during MR procedures for various reasons. For example, the pattern of rf absorption or the coupling of radiation to biological tissues is highly dependent on the organism's size, anatomic factors, the duration of exposure, the sensitivity of the involved tissues, and a myriad of other variables.^{1,3,4,17,25} Of further note is that there is no laboratory animal that sufficiently 'mimics' the thermoregulatory responses of a human subject to heating in regards to the activation of heat dissipation mechanisms (i.e., the alterations in regional circulations and sweating that occur in response to a heat load). Therefore, experimental results obtained in laboratory animals cannot be simply 'scaled' or extrapolated to predict thermoregulatory or other physiological changes in human subjects exposed to rf radiation-induced heating during MR procedures.^{17,18,25}

Elaborate mathematical models have been devised to predict 'worst-case' scenarios of how human subjects may respond to the rf energy that is absorbed during MR procedures.^{26–28} However, a recognized major limitation of mathematical modeling is that it is difficult to account for the numerous critical variables (i.e., circulatory abnormalities, amount of subcutaneous, 'insulative' fat, etc.) that can affect the thermoregulatory responses of human subjects, particularly patients.

Many individuals that are exposed to rf radiation during MR procedures have some health condition or are taking medication that can alter or impair their ability to dissipate a heat load. More importantly, none of the mathematical models developed to predict thermal responses to rf radiation

have been validated. Nevertheless, mathematical models that presume a 'worse case scenario' may approximate a given situation during an MR procedure that may be of some use. More precise characterization of thermal responses to rf radiation-induced heating requires experiments performed in human subjects. Several investigations have been conducted in recent years that have yielded extremely beneficial and important data about the human thermoregulatory system and other physiological reactions to the tissue heating produced by rf radiation during MR procedures.

2 CHARACTERISTICS OF RF RADIATION-INDUCED HEATING DURING MR PROCEDURES

The physical dimensions and configuration of the tissue in relation to the incident wavelength of rf radiation are important factors that determine the relative amount and pattern of energy that is absorbed by the organism.¹⁻⁴ If the tissue size is large in relation to the incident wavelength, energy is predominantly absorbed on the surface.¹⁻⁴ If it is small relative to the wavelength, there is little absorption of rf power.¹⁻⁴

The most efficient absorption of rf energy occurs when the tissue is approximately 50% the size of the incident wavelength and this frequency of maximum absorption is known as the 'resonant frequency'. Exposure to a resonant frequency of rf power is considered to be the most hazardous because of deep and, often times, uneven absorption patterns.¹⁻⁴ In consideration of this, rf radiation is believed to be a unique source of tissue heating due to its ability to penetrate superficial tissues and directly heat internal sites of the body at certain incident wavelengths.^{2,3}

Tissue heating that results from the rf radiation used for MR procedures is primarily caused by magnetic induction with a negligible contribution from the electric fields.¹²⁻²¹ Therefore, ohmic heating of tissue during MR procedures occurs the most at the surface or periphery and is minimal at the center of the body. Predictive calculations and measurements obtained in phantoms and in human subjects exposed to MR imaging support this pattern of temperature distribution.¹²⁻²¹

The actual increase in tissue temperature caused by exposure to rf radiation is dependent on a variety of factors associated with the thermoregulatory system of the individual and the surrounding environment.^{2,3,15-19} When subjected to a thermal challenge, the human body loses heat by means of convection, conduction, radiation, and evaporation. Each of these mechanisms is responsible to a varying degree for heat dissipation as the body attempts to maintain thermal homeostasis.^{2,3} If the thermoregulatory effectors are unable to dissipate the heat load, then storage of heat occurs and there is an increase in local and/or overall tissue temperatures.^{2,3}

There are various health conditions that may affect an individual's ability to tolerate a thermal challenge. These conditions include: cardiovascular disease, hypertension, circulatory abnormalities, diabetes, fever, old age, obesity, and others.²⁹⁻³⁵ Various types of medications (diuretics, beta blockers, calcium blockers, amphetamines, muscle relaxers, sedatives, vasodilators, vasoconstrictors, inotropes, etc.) can also alter the thermoregulatory responses to a heat load, especially if the medications produce alterations in peripheral circulations. Additionally, certain medications are

known to augment the heating that is caused by exposure to rf radiation.^{36,37}

The environmental conditions that exist in and around the MR system will also affect the tissue temperature changes of the individual that occur during rf radiation-induced heating. During an MR procedure, the amount of tissue heating that occurs and concomitant exposure to rf radiation that is tolerable are dependent upon environmental factors that include the ambient temperature, relative humidity, and the presence and amount of air flow.

3 MR PROCEDURES AND THE SPECIFIC ABSORPTION RATE (SAR) OF RF RADIATION

The thermoregulatory and other physiological changes that a human subject displays in response to exposure to rf radiation are dependent on the amount of energy that is absorbed. Specific absorption rate or SAR is the term that is used to describe the absorption of rf radiation.¹⁻⁴ The SAR is the mass normalized rate at which rf power is coupled to biological tissue and is typically indicated in units of watts per kilogram (W kg^{-1}).¹⁻⁴ The relative amount of rf radiation that an individual encounters during an MR procedure is usually characterized for safety reasons with respect to the whole body averaged level and peak SAR levels (i.e., the SAR averaged in 1 g of tissue) of the exposure.

Of note is that measurements or estimates of SAR are not trivial, particularly in human subjects, and there are several methods of determining this parameter for the purpose of dosimetry of rf energy associated with MR imaging or spectroscopy.¹²⁻²² The SAR that is produced during an MR procedure is a complex function of numerous variables including the frequency (which, in turn, is determined by the static magnetic field strength of the MR system), the type of rf pulse used (i.e., 90° or 180°), the repetition time, the pulse width, the type of rf coil used (i.e., transmit/receive body coil or send/receive surface coil), the volume of tissue contained within the coil, the resistivity of the tissue, the shape of the anatomical region exposed, the orientation of the body to the field vectors, as well as other factors.¹²⁻²²

4 ASSESSMENT OF THERMAL AND OTHER PHYSIOLOGICAL RESPONSES TO RF RADIATION-INDUCED HEATING DURING AN MR PROCEDURE

Obtaining thermal and other physiological measurements in human subjects within the harsh electromagnetic environment associated with the MR system is not a simple task. The high-field strength static magnetic field of the MR system can create missiles out of monitors because these devices usually contain ferromagnetic components.³⁹⁻⁴² In addition, the static, gradient, and rf electromagnetic fields may adversely interfere with the proper operation of the monitoring equipment.³⁹⁻⁴² In turn, the monitors themselves may produce subtle or significant imaging artifacts during operation by generating 'rf noise' that can significantly distort the quality of the MR images.³⁹⁻⁴²

In consideration of the above, monitors must be specially modified and then rigorously tested prior to use in the MR environment. Otherwise, the data pertaining to thermal and other physiological responses may be erroneous.

Currently, there are a variety of MR-compatible monitors, as well as other patient support devices that are commercially available.^{39–42} Every physiological parameter that may be obtained in the critical care unit or operating room may be recorded during an MR procedure, including heart rate, oxygen saturation, end-tidal carbon dioxide, respiratory rate, blood pressure, cutaneous blood flow and, most importantly, body and skin temperatures.^{39–42}

For the assessment of thermal responses during an MR procedure, volunteer subjects or patients have been continuously or semicontinuously monitored throughout the experimental procedures using several different types of devices. Sublingual pocket or tympanic membrane temperature (note that there is a good relationship between temperatures measured in the sublingual pocket or tympanic membrane and esophageal temperatures) are typically obtained immediately before and after MR procedures using sensitive electronic thermometry or infrared devices.^{43–53} Skin temperatures may also be measured immediately before and after MR procedures using highly accurate, infrared thermometry or thermographic equipment.^{43–53} Body and skin temperatures measured at multiple sites can be recorded before, during, and after MR procedures using a fluoroptic thermometry system that is unperturbed by electromagnetic radiation.⁴² Heart rate, oxygen saturation, blood pressure, respiratory rate, and cutaneous blood flow, which are important physiological variables that change in response to a thermal load, are typically monitored before, during, and after MR procedures to assess the reaction of the thermoregulatory system of human subjects exposed to rf radiation-induced heating. All of these parameters are recorded with MR-compatible devices that have been extensively tested and demonstrated to provide sensitive and accurate data.^{43–53}

5 THERMAL AND OTHER PHYSIOLOGICAL RESPONSES TO RF RADIATION-INDUCED HEATING DURING AN MR EXAMINATION

As previously mentioned, the increase in tissue temperature caused by exposure to rf energy during an MR procedure depends on multiple physiological, physical, and environmental factors including the status of the patient's thermoregulatory system, underlying health conditions, duration of exposure, the rate at which energy is deposited, the ambient temperature, humidity, and airflow over and around the patient within the MR system. Although the primary cause of tissue heating during MR procedures is attributed solely to rf radiation, it should be noted that various reports have suggested that exposure to static magnetic fields used for MR procedures may also cause temperature changes.^{55,56}

The mechanism(s) responsible for such an effect resulting from exposure to the static magnetic field remains unclear, but the results of these studies have warranted investigations in human subjects to determine if there is any contribution of the static magnetic field to the temperature changes that may be observed during an MR procedure. Therefore, studies have been conducted in human subjects exposed to a 1.5 T static

magnetic field in order to determine if there was any effect on body and/or skin temperatures.^{57,58} The data from these investigations revealed that there were no statistically significant alterations observed in any of the recorded temperature or other physiological parameters.^{57,58} Tenforde⁵⁹ examined this phenomenon, as well, in laboratory animals exposed to static magnetic fields of as high as 7.55 T and also reported no effect. As far as the potential for production of heat by gradient magnetic fields is concerned, this is not believed to occur as a result of the conventional pulse sequences used for present-day clinical MR procedures.¹⁶

The first study of human thermal responses to rf radiation-induced heating during an MR procedure was conducted by Schaefer et al.⁶⁰ Temperature changes and other physiological alterations were assessed in volunteer subjects exposed to relatively high whole body averaged SARs (i.e., approximately 4.0 W kg^{-1}). The data indicated that there were no excessive temperature elevations or other deleterious physiological consequences related to this exposure to rf radiation.⁶⁰

Several studies were subsequently conducted involving volunteer subjects and patients undergoing clinical MR procedures with the intent of obtaining information that would be applicable to the patient population typically encountered in the MR setting.^{43–45,47,50,52,54,60–62} The whole body averaged SARs ranged from approximately 0.05 W kg^{-1} (i.e., for MR procedures involving imaging with a transmit/receive head coil) to 4.0 W kg^{-1} (i.e., for MR procedures involving the imaging of the spine or abdomen with a transmit/receive body coil).^{43–52} These studies demonstrated that changes in body temperatures were relatively minor (i.e., less than 0.6°C). There tended to be statistically significant increases in skin temperatures that were also of no serious physiological consequence. Furthermore, there were no associated deleterious alterations in any of the hemodynamic parameters that were assessed during these investigations (i.e., heart rate, blood pressure, and cutaneous blood flow).

Of further note is that there was a poor correlation between body or skin temperature changes versus whole body averaged SARs during clinical MR imaging. This is not unusual considering all of the variables that may alter thermal responses in a patient population. Therefore, the thermal reactions to a given SAR may be quite variable depending on the individual's own thermoregulatory system and the presence of one or more underlying condition(s) that may alter or impair the ability to dissipate heat.

An extensive thermophysiological investigation using multiple fluoroptic thermometry probes that are unperturbed by electromagnetic fields demonstrated that human subjects with normal thermoregulatory systems exposed to MR imaging at whole body averaged SAR levels up to 4.0 W kg^{-1} had no statistically significant increases in body temperatures, and have statistically significant elevations in skin temperatures that were not excessive.⁵⁰ The results of this study indicated that the SAR recommendations issued by some of the regulatory agencies (i.e., United States Food and Drug Administration and United Kingdom's National Radiological Protection Board) for exposure to rf radiation for patients with normal thermoregulatory function may be too conservative.⁵⁰

Research has been performed in volunteers exposed to MR imaging performed at a whole body averaged SAR of 6.0 W kg^{-1} in cool (22°C) and warm (33°C) environments in order to characterize thermal and other physiological

responses to this high exposure to rf energy, since some of the newly developed pulse sequences have very high SARs associated with their use.⁵³ Tympanic membrane temperature, six different skin temperatures, heart rate, blood pressure, oxygen saturation, and skin blood flow were monitored before, during, and after exposure to the rf energy. In the cool environment, there were statistically significant increases in tympanic membrane, abdomen, upper arm, hand, and thigh temperatures as well as heart rate and skin blood flow. In the warm environment, there were statistically significant increases in tympanic membrane, hand, and chest temperatures as well as systolic blood pressure and heart rate. These data indicate that MR imaging performed at 6.0 W kg^{-1} can be physiologically tolerated by individuals with a normal thermoregulatory function.⁵³

Of additional note is that the subjective perception of tissue heating was greater when the subjects underwent MR imaging at an SAR of 6.0 W kg^{-1} in the cool environment compared with their experience in the warm environment. This indicates that it would not be useful to precool subjects that will subsequently undergo high SAR procedures in order to help them better tolerate these procedures, as has been suggested by some researchers and manufacturers of MR systems.

6 MR PROCEDURES AND TEMPERATURE-SENSITIVE ORGANS: THE TESTIS AND EYE

Certain human organs that have reduced capabilities for heat dissipation, such as the testis and eye, are particularly sensitive to elevated temperatures. Therefore, these are primary sites of potentially harmful effects if rf radiation exposures during MR procedures are excessive.^{12–19,22}

Laboratory investigations have demonstrated detrimental effects on testicular function (i.e., a reduction or cessation of spermatogenesis, impaired sperm motility, degeneration of seminiferous tubules, etc.) caused by rf radiation-induced heating from exposures sufficient enough to raise scrotal and/or testicular tissue temperatures between $38\text{--}42^\circ\text{C}$.⁷ Scrotal skin temperatures (which are an index of intratesticular temperatures because a high correlation has been demonstrated between intratesticular and scrotal skin temperatures)⁶³ were measured in volunteer subjects undergoing MR imaging at a whole body averaged SAR of 1.1 W kg^{-1} .⁴⁸ The largest change in scrotal skin temperature was 2.1°C and the highest scrotal skin temperature recorded was 34.2°C .⁴⁸ These temperature changes were below the threshold known to impair testicular function.^{7,48} However, inordinately heating the scrotum during MR imaging could exacerbate certain pre-existing disorders associated with increased scrotal/testicular temperatures (e.g., acute febrile illnesses, varicocele, etc.) in patients who are already oligospermic, and could lead to temporary or permanent sterility. Therefore, additional studies designed to investigate these issues are needed, particularly if patients are subjected to MR-procedure SARs that are higher than those previously evaluated (which is entirely possible, since there is a trend to use some of the newly developed pulse sequences that have associated high SARs to image the scrotum).

Dissipation of heat from the eye is a slow and inefficient process due to its relative lack of vascularization.⁶ Acute near-field exposures of rf radiation to the eyes or heads of laboratory animals have been demonstrated to be cataractogenic as a result of the thermal disruption of ocular tissues if the exposure is of a sufficient intensity and duration.⁶ An investigation conducted by Sacks et al.⁶⁴ revealed that there were no discernible effects on the eyes of rats produced by MR procedures at exposures that far exceeded typical levels used in the clinical setting. However, as previously indicated, it may not be acceptable to extrapolate these data to human subjects considering the coupling of rf radiation to the anatomy and the tissue volume of laboratory rat eyes compared with those of human subjects.

Corneal temperatures (corneal temperature is a representative site of the average temperature of the human eye)⁶⁵ have been measured in patients undergoing MR imaging of the brain using a transmit/receive head coil at peak SARs up to 3.1 W kg^{-1} .⁴⁶ The largest corneal temperature change was 1.8°C and the highest temperature measured was 34.4°C . A more recent study⁴⁹ examined corneal temperatures in patients with suspected ocular pathology who underwent MR imaging using a special eye coil. Again, there were no excessive corneal temperature elevations. Because the temperature threshold for radiation-induced cataractogenesis in animal models has been demonstrated to be between $41\text{--}55^\circ\text{C}$ for acute near-field exposures,⁶ it does not appear that clinical MR imaging using a head coil or an eye coil has the potential to cause thermal damage to ocular tissue. The effect of MR procedures performed using higher SARs on ocular tissue remains to be determined.

7 MR PROCEDURES AND 'HOT SPOTS'

Theoretically, rf radiation 'hot spots' caused by an uneven distribution of rf power may arise whenever current concentrations are produced in association with restrictive conductive patterns.^{13–22} There has been the suggestion that rf radiation 'hot spots' may occur during an MR procedure and generate thermal 'hot spots' under certain conditions. Because rf radiation is mainly absorbed by peripheral tissues, thermography has been used to study the heating pattern associated with MR procedures performed at high whole body averaged SARs.^{44,54} This research demonstrated that there was no evidence of surface thermal 'hot spots' related to performing MR imaging in human subjects. The thermoregulatory system apparently responds to the thermal load induced by rf radiation by distributing the heat, producing a 'smearing' effect of the surface temperatures.^{44,54} However, there is a possibility that internal thermal 'hot spots' may develop during an MR procedure. This issue is currently undergoing investigation in human subjects.

Shuman et al.⁶⁶ reported that significant temperature rises occur in the internal organs of laboratory dogs produced during MR imaging performed with high SARs. Of further note is that this study was conducted on anesthetized animals and is unlikely to be pertinent to conscious adult human subjects because of the previously discussed factors related to the physical dimensions of the animals, the fact that an anesthetic agent was used which may affect thermoregulation, as well as due to the dissimilar thermoregulatory systems of these two species. However, the data obtained by Shuman

et al.⁶⁶ may have important implications for the use of MR procedures in pediatric patients because this patient population is typically sedated or anesthetized for MR examinations and the physical dimensions of the dog are comparable with those of the pediatric population. Obviously, research is required to examine this issue more closely.

8 FUTURE STUDIES OF RF RADIATION-INDUCED HEATING DURING MRI

Several new pulse sequences have been developed and are currently undergoing clinical trials that use high levels of rf energy for their implementation.^{67,68} For example, the latest versions of the 'fast spin echo' (FSE) and magnetization transfer contrast (MTC) pulse sequences may use SARs that easily exceed whole body averaged SARs ranging between 4–8 W kg⁻¹.

The FSE pulse sequences are hybrids of RARE (rapid acquisition relaxation enhanced) pulse sequences and have increased rf power depositions compared with conventional spin echoes.⁶⁹ This is due to the high density of 180° refocusing pulses used for these pulse sequences.⁶⁹ MTC pulse sequences involve the use of selective and continuous saturation of macromolecular protons utilizing an off-resonance rf pulse during the implementation of the technique, so that the rf power deposition is of considerable concern.⁶⁸ This is particularly a potential problem in MR imaging examinations that involve large body parts that require rf transmission using the body coil.

Both the FSE and MTC pulse sequences offer several important clinical advantages over conventional pulse sequences. However, before FSE and MTC pulse sequences are routinely used for all clinical applications, investigations must be performed to assess and characterize thermal and other physiological responses to the rf radiation-induced heating related to these new pulse sequences. Therefore, studies are currently examining the human thermoregulatory responses to SARs that are even higher than those that have been studied in recent years. Preliminary results of these investigations are encouraging with respect to the ability of individuals with normal thermoregulatory function to tolerate MR examinations that require high SARs.⁵³

Other MR procedures where rf radiation-induced heating may cause appreciable increases in tissue include ¹H decoupling, Overhauser enhancement, and burst sequences used in MR spectroscopy. Therefore, these MR procedures will need to be evaluated in the future in order to determine the relative safety of performing these applications in patient populations.

In addition, there are now several 4.0 and one 5.0 T whole body MR systems that are being used for a combination of imaging and spectroscopy in human subjects. These devices use approximately 7–10-times as much rf energy as 1.5 T MR scanners during MR procedures.^{70,71} Investigations evaluating thermal responses in human subjects will also need to be performed to assess the safety of these powerful devices.

Additional studies are presently needed in order to assess the thermal responses of patients with conditions or medications that may impair their ability to dissipate heat before subjecting them to MR procedures that require high SARs. There is currently an ongoing effort to characterize the thermal and

other physiological responses of these various patient groups to rf radiation-induced heating during MR examinations using high SARs.

Elevated body temperature is teratogenic in various animals, including primates.^{7,9,10} Research studies have shown that excessive heat may cause birth defects and prenatal mortality when the body temperature of the pregnant mother reaches 40–44 °C.^{7,9,10} Lower, but still elevated, body temperatures may significantly increase the incidence of reduced body weight, cause physiological changes, or behavioral alterations.^{7,9,10} Increased temperatures that specifically result from exposure to rf radiation have been reported to affect adversely the developing embryo.^{7,9,10} To date there have been no studies designed to examine the thermal effects of rf radiation-induced heating during MR procedures performed in pregnant patients. Therefore, experiments will be needed to assess the potential adverse effects of rf radiation with respect to pregnant patients undergoing MR procedures.

Biographical Sketches

Frank G. Shellock. b 1954. B.S., 1976, Loyola-Marymount University, Los Angeles, CA, M.S., Biology, 1980, California State University, Ph.D., 1982, Physiology, Columbia Pacific University, San Rafael, CA. Over 300 publications. Research specialties: bioeffects of MR procedures; bioeffects of electromagnetic fields; MR imaging of skeletal muscle, cartilage, and other musculoskeletal applications; kinematic MR imaging; dynamic MR imaging of the upper airway; MR mammography.

Health and Safety Aspects of Human MR Studies

Thomas F. Budinger

University of California, Berkeley, CA, USA

1 HISTORICAL DEVELOPMENT

The study of the biological and human health effects of static and oscillating magnetic fields started over 100 years ago and currently there are well over 700 published reports on biological effects. The earliest well-known measurement of magnetic field effects in human beings is the induction of visual phenomenon (phosphenes) by E fields induced by switched magnetic fields near the human eye in experiments by d'Arsonval in 1896.¹ The best-known effect of static field was the observation of torque on biological assemblages such as retinal rods, chloroplasts, and sickle cells in magnetic fields below 1 T reported in the early 1970s.²⁻⁴ A third phenomenon observed at that time was electrocardiograph (ECG) abnormalities in monkeys placed in magnetic fields; however, this effect was shown to be the superimposition of electric potentials induced by flow of blood, which is a conductor, across the field flux lines.^{5,6} Examination of safety and human physiology experiments in MR commenced at the end of the 1970s⁷ with research continuing to the present.⁸⁻¹⁶ Safety issues continue to evolve because of initiatives to carry out studies in humans at higher static fields and with more rapidly switching gradients than currently employed. The use of MR in subjects with prostheses and the contemporary application of MR in therapy present safety problems in all fields.

Some effects scale with the square of the field increase and some thresholds for physiological effects are not well defined. However, the fundamental physics underlying evaluations of the safety and health effects of static and oscillating magnetic fields is not complex; nor is the validated interaction of magnetic static and oscillating fields with tissues and human organ systems as mysterious as is sometimes implied.^{17,18} The controversial issues of the biological effects of power-line E fields and power frequency time-varying magnetic fields ($0.1 \mu\text{T s}^{-1}$) are discussed elsewhere.^{10,19}

2 STATIC MAGNETIC FIELDS

2.1 Physical Effects

Four physical effects that have a potential for the interaction of magnetic fields with tissues are (i) the translational force, which is important in assessing the effect of ferromagnetic projectiles; (ii) the twisting force or torque on molecules, assemblages of molecules, or ferromagnetic objects implanted in tissues; (iii) the force on ions or charged objects moving in

a magnetic field; and (iv) the magnet's hydrodynamic retarding force.

The translational or projectile force (F) on a ferromagnetic object is given by:

$$F = H\chi V dH/dx \quad (1)$$

where H is the external field, χ is the susceptibility, and V is the volume. The magnetic flux density (B) in an object is the result of the magnetizing field (H) to which the object is exposed. Omitting the permittivity of free space and recognizing that the susceptibility of tissues is very small (e.g., -10^{-6}), H and B are used interchangeably. This equation shows that the magnitude of the force depends on the susceptibility of the object, the field strength, and the gradient of the field strength. Because the magnetization of human tissues is so small, there is an insignificant force on the body. For example, the force on 1 g water is -1.4×10^{-4} N in a gradient of 0.15 T m^{-1} and a field of 1.5 T but the force on 1 g iron is 2.8 N (20 000 times greater in the opposite direction), about the force of gravity on a 0.6 lb (270 g) mass. This force scales as mass; consequently, a 0.5 lb (225 g) tool would become a force equivalent to a 134 lb (61 kg) weight accelerated by gravity.

The maximum magnetic force around a magnet is related to B by dB/dt and is $8.8 \text{ T}^2 \text{ m}^{-1}$ for a 4 T magnet. This results in a force on red blood cells relative to plasma that is less than 3% of the gravitational force, and can therefore have no significant effect on living organisms.¹⁵ There will be no force on an object inside the bore of a magnet where dH/dx is 0 no matter what the susceptibility is unless there is a variation of susceptibility across the object, in which case the imbalance in magnetization will result in a *torque*.

The magnetization energy or interaction energy of a field H with biological molecules of diamagnetic susceptibility is given as

$$W = -\frac{1}{2} \int_v H \bar{\chi} H dv \quad (2)$$

where $\bar{\chi}$ is the magnetic susceptibility tensor and the integration is carried out over the volume of the biologic structure (v). Normally the energy is similar in magnitude to the thermal energy (4×10^{-21} J) but if cell structures or molecular assemblages have structures that result in different susceptibilities in different axes, as with sickle cells,²⁰ retinal rods,³ and chloroplasts,² then in vitro a torque will cause the structures to orient along the magnetic field lines in accord with

$$W = -\frac{v}{2} (\chi_r + |\chi_e - \chi_r| \cos^2 \theta |H|^2) \quad (3)$$

where v is the volume of the structure, χ_r and χ_e are the susceptibilities for the short and long axes of the biological molecule or assemblage, respectively, and θ is the angle between the field H and the long axis.

Macromolecular assemblies such as lipid bilayers can have relatively large magnetic moments. It has been hypothesized that changes in the orientation of ordered structures in the membrane bilayer caused by magnetic fields may lead to permeability changes, and changes in Ca^{2+} transport in lymphocytes in vitro have been reported at 7.5 T.²¹ However, there are no reported physiological effects in animals exposed

at 9 T (M. Garwood, University of Minnesota, personal communication, 1998) and humans exposed at up to 8 T (A. Kangarlou, Ohio State University, personal communication, 1998).

The third force associated with conductors moving in a magnetic field is given by the Lorentz force equation in the absence of electric fields:

$$\mathbf{F} = q(\mathbf{v} \times \mathbf{B}) = q(|\mathbf{v}| \cdot |\mathbf{B}| \sin \theta) \quad (4)$$

where q is a unit positive charge, $\mathbf{v}$ is the velocity and θ is the angle between the velocity vector and the induced field $\mathbf{B}$.

Negative ions will move in opposite directions, resulting in a separation of charges or an electric potential (emf),

$$\text{emf} = |\mathbf{v}| \cdot |\mathbf{B}| (\sin \theta) d \quad (5)$$

where d is the distance or width of the flow. For blood flowing at 0.4 m s^{-1} , in a 0.016 m (16 mm diameter) aorta at right angles (i.e., $\sin \theta = 1.0$) to a field in the tissues of 1 T , the electric potential will be 6.4 mV . When measured on the human torso, this will appear as a signal of a few millivolts superposed on the ECG (Figure 1). This phenomenon was first observed in 1967⁶ with detailed studies since.²² It presents a safety problem because the artefact interferes with monitoring of patient heart stress by ECG during MRI examinations to evaluate heart function (Figure 1). The $\mathbf{E}$ field for an aorta of 1.6 cm is 0.4 V m^{-1} . A potential of approximately 64 mV across the aorta is predicted in a 10 T field; however, there is no suggestion that this could be a hazard: the $\mathbf{E}$ field is 4 V m^{-1} , which is below that causing cardiac stimulation and orders of magnitude below the local $\mathbf{E}$ field (10^8 V m^{-1}) across membranes of sub-micrometer thickness. The effective DC electric field acting in a person traveling across the USA in an airplane at 500 mph (223.5 m s^{-1}) is about 10 mV m^{-1} .

Currents associated with nerve firing could be distorted by large magnetic fields. This would be reflected in the nerve conduction velocity, and decreases of 10% at 18 T have been predicted.²³ Studies at up to 7.5 T have shown no changes.²² Earlier reports of detected changes have been shown to be the result of inadequate temperature control as conduction velocity changes by 1% for a temperature change of $0.1\text{--}0.2^\circ\text{C}$.

Magneto-hydrodynamic effects can result in some retardation of flow in blood, a conductor. The effect is greatest in large

vessels. Blood flowing in a magnetic field creates an electric field; however, ions in this $\mathbf{E}$ field moving perpendicular to the magnetic field will experience a force in a direction that is opposite to the direction of blood flow. This comes from the relationship

$$\mathbf{F} \propto \mathbf{E} \times \mathbf{B} \quad (6)$$

Substitution of Equation (4) gives:

$$\mathbf{F} \propto q(\mathbf{v} \times \mathbf{B}) \times \mathbf{B}$$

The force direction is opposite to the vector direction of the flowing blood. The retardation of flow will not be significant in a 10 T field, based on our previous studies at 4.7 T . Analyses prior to 1990 which suggested a strong effect were found to be in error and no significant effect will be observed even at 10 T .²⁴

Other forces, the NMR effect, the cyclotron resonance effect, and ion paramagnetic resonance effect are not significantly relative to thermal forces and tissue viscosity to warrant concern regarding safety.¹⁰

2.2 Health Effects

Though measureable effects of static magnetic fields have been observed in animals and humans, there are no known or expected harmful physical or physiological effects of fields as high as 10 T . The naturally occurring magnetic field of the Earth can influence the swimming direction of a bacterium containing magnetite particles.²⁵ The Earth's magnetic field can also influence the migratory pattern of birds by a mechanism believed to be associated with magnetite.²⁶ Sharks, skates, and rays contain internal organs that use the induced currents generated by the animal swimming through the Earth's magnetic field as a navigational compass.^{4,27}

Though not considered to be harmful, dizziness and stimulation of nerves in the palate associated with head movement in the field have been reported at 4 T . Dizziness or nausea could be caused by motion of the endolymph in the semicircular canals¹⁴ or by a magnetomechanical mechanism²⁸ and subject motion within the magnetic field. Subject evaluation after exposure to 4 T fields has not revealed any lasting effects.^{14,29} Additionally, as noted earlier, the ECG changes at 1.5 T and above³⁰ can be explained as insignificant effects associated with the static fields or magnetic environment.

Epidemiological studies have followed workers in aluminum plants who are exposed to fields up to 29 mT ,^{31–34} radiation workers near accelerators and bubble chambers,²⁸ and technicians in the MR environment.³⁵ Though Milham in 1985 reported increased disease incidence in one aluminum plant survey,³⁶ other studies have not shown a deleterious effect.

3 TIME-VARYING MAGNETIC FIELDS

3.1 Physical Effects

In NMR, rapidly oscillating magnetic fields known as rf pulses are used to stimulate the NMR signal and less rapidly

Figure 1 Static field effects on human electrocardiograph signals. (a) Normal trace from outside the magnetic field. (b) Trace is the resultant electric potential from both the normal signal and the induced potential of blood flowing in a magnetic field (1.5 T) [see Equation (8)]

oscillating or time-varying magnetic fields are used to provide the gradients for imaging. The typical effect from the oscillating fields is the induction of E fields, which generate heat at high frequencies and neural or neuromuscular stimulation at low frequencies. Heat or pain thresholds limit the extent of the MR procedure. Though E fields are produced by high- or low-frequency oscillations, it is convenient to consider the main effect of low-frequency oscillations as an electrical effect and the effects of high-frequency or rf fields as a heating phenomenon.

Gradient fields of up to 10 mT m^{-1} are used in contemporary MRI instruments, with some recent installations at 20 mT m^{-1} . Functional MRI applications use rise times such that the value of dB/dt approaches 50 T s^{-1} . If 8–10 T fields are to be used to improve the spatial resolution of ^1H imaging, the gradient strength must increase. Both safety and engineering considerations may limit the maximum useful gradient field, but plausible design goals lie in the range $20\text{--}50 \text{ mT m}^{-1}$. The force on ferromagnetic objects, including components of the magnet and coils, is proportional to the gradients. But the rate at which these gradients are achieved is a critical factor for human studies. For example, if the gradient is switched from 0 to 10 mT m^{-1} in $200 \mu\text{s}$, dB/dt is 50 T s^{-1} at the end of a 1 m long gradient coil and the E field around a 0.4 m diameter abdomen is 5 V m^{-1} . This is near the threshold for neuromuscular stimulation of 6 V m^{-1} .

The generation of a voltage from oscillating fields is derived from Faraday's Law

$$\text{emf} = \frac{dB}{dt} \pi r^2 \quad (7)$$

where B is the magnetic field in the tissue and πr^2 is the area exposed to the time-varying field. Since the electric field is the voltage per distance around the loop $2\pi r$, Equation (7) becomes

$$E = \frac{-r}{2} \frac{dB}{dt} \quad (8)$$

For a switched field of 10 T s^{-1} and a body radius of 0.2 m, the E field will be 1 V m^{-1} at the surface of the body.

For a sinusoidal oscillation

$$B(t) = B_{\max} \sin 2\pi f t \quad (9)$$

where f is the frequency and $B_{\max}$ is the amplitude of the sinusoidal oscillating magnetic fields; therefore,

$$\text{dB}/\text{dt} = 2\pi f B_{\max} \quad (10)$$

and Equation (8) becomes

$$E = -r\pi f B \quad (11)$$

The current density is the E field multiplied by the tissue conductivity (σ); consequently the relationship between the tissue current density and the time-varying magnetic field is

$$J = -r \frac{\sigma}{2} \frac{dB}{dt} \quad (12)$$

For a loop radius of 10 cm, a conductivity of 0.2 s m^{-1} and a dB/dt of 1 T s^{-1} , an E field of 0.05 V m^{-1} and a current density of 0.01 A m^{-2} or $1 \mu\text{A cm}^{-2}$ would be expected. These fields and associated current densities can be compared with the naturally occurring fields in the body: 1 V m^{-1} in the brain and 1 mV m^{-1} at the scalp. Fields at the surface of the heart are $1\text{--}10 \text{ V m}^{-1}$ and at the surface of the chest are $10\text{--}50 \text{ mV m}^{-1}$. Near power lines, where fields of 10 kV m^{-1} occur, the body E field is 10 mV m^{-1} ; for 60 Hz and a $B_{\max}$ of 0.5 G, the induced body E fields are 2 mV m^{-1} .

Time-varying fields of the amplitudes used in MRI are not capable of interfering with cardiac rhythm, but these rapidly changing gradients can induce electrical peripheral neuromuscular stimulation.

3.2 Health Effects

Since a time-varying field induces currents in the body proportional to dB/dt , exposure standards are generally listed in Tesla/second, the rate of field change, or milliamperes per square meter, the induced current density in the tissue. For complex waveforms, a root-mean square measure is used, or the rate of field change is scaled by a function of the pulse duration.

The threshold for neuromuscular stimulation of the torso by sinusoidal fields is 60 T s^{-1} at 1 kHz.^{37,38} This threshold is the rate of change at which the sensation of a mild electric shock is reported by the subject. The E field for this stimulation is 6 V m^{-1} , or a current density of about 1.2 A m^{-2} for a path loop of 40 cm diameter. For the head, the effective loop radius for the z axis is less than that for the torso and the threshold is higher; however, the transverse field is such that even for a head coil, the threshold for slight pain is $50\text{--}60 \text{ T s}^{-1}$. The coil type, coil size, and geometry, as well as the rise time and gradient, are all important factors in the calculation of the E field that will be induced. The primary hazard associated with currents in the body is interference with neuromuscular function; however, before this occurs, the pain of an electric shock will be felt. Current densities greater than 20 A m^{-2} when induced by direct electrical contact can cause irreversible cardiac fibrillation; alternating electrical current densities of 5 A m^{-2} can cause cardiac ectopic events. It is erroneous to extrapolate the 1.2 A m^{-2} current density for a body coil operating at 60 T s^{-1} to that expected at the heart because the conductive loop is only 10 cm. Consequently, the current density is likely to be 0.3 A m^{-2} or 30 times larger than endogenous current densities of 10 mA m^{-2} .

The effect on nerves of time-varying fields is frequency dependent, being most sensitive near 60 Hz for mammalian nerve cells. Applied currents as small as 10 mA m^{-2} at 60 Hz have been observed to cause reversible changes in the nerve firing rate in in vitro preparations of nerves in petri dishes. This threshold is dependent on the frequency and the relative orientation of the current and the nerve, and a threshold in the body may be substantially higher.

Visual effects (magnetophosphenes) are reported at 2 T s^{-1} for 30 Hz. As the flicker fusion threshold for visualizing phosphores is about 40 Hz, one would not expect to observe phosphores at switched field rates greater than 500 Hz, which are those normally encountered in MRI exposures.

4 THE RADIOFREQUENCY HEATING THEORY

Heating by rf waves during MR occurs via magnetic induction [Equation (11)] with negligible ohmic contributions. The power absorbed by the tissue is given as power divided by mass m , or specific absorbed power, SAR (watts kg^{-1}):

$$\text{SAR} = \frac{\sigma E^2}{2\rho} \quad (13)$$

where ρ is the tissue density (usually 1 kg l^{-1}). However, the induced E fields vary over the body dependent on the loop diameter [i.e., the value of r in Equation (11)]. Heating will occur predominantly at the surface of the body with relatively little deep body heating. For a homogeneous sphere of radius R , the average SAR will be

$$\text{SAR}_{\text{sphere}} = \frac{\sigma D E^2 R^2}{20\rho} \quad (14)$$

where D is the duty cycle. The rf power ratio between the outer radius, R , and a smaller radius, r , is:¹³

$$1 - \frac{r^5}{R^5} \quad (15)$$

The peak power is 2.5 times the average power. The mean temperature (T) elevation can be determined from

$$\Delta T(^{\circ}\text{C}) = \frac{\text{SAR} \times \text{time (s)}}{\text{specific heat}} \quad (16)$$

For a specific absorbed power of 4 W kg^{-1} for 10 min, the maximum temperature rise is equal to 0.7°C using the soft tissue specific heat of $3.5 \text{ kJ kg}^{-1} \text{ }^{\circ}\text{C}^{-1}$ ($0.83 \text{ kcal kg}^{-1} \text{ }^{\circ}\text{C}^{-1}$). The expected increase in signal to noise with field or frequency increases is shown in Figure 2.

Heating by rf waves at the higher fields (i.e., 4–10 T) and the corresponding higher frequencies for protons (i.e. 170–430 MHz) can be a serious limitation. Theoretical and experimental phantom studies^{39,40} on a homogeneous sphere simulating the human head show the increase in absorbed power with frequency (Figure 3). Studies using a realistic layered model show that the SAR increases quadratically with f below 200 MHz, and linearly above 250 MHz.^{41,42} Even at 10 T, a 30° , 2 ms sinc pulse with 10 zero-crossings can be applied as fast as once every 13 ms for ^1H and once every 26 ms for ^{31}P and ^{23}Na without any local heating. Theory also shows that fast imaging of the head with soft rf pulses can be performed at field strengths as high as 10 T. Localized spectroscopic studies of ^1H , ^{31}P , ^{23}Na , and ^{13}C with surface coils are feasible up to 10 T, although localized heating can reach a harmful level.

4.1 Radiofrequency Heating in Humans

Temperature elevation from the absorbed energy associated with the rf power is the major measurable physiological effect of present and future MR imaging and human spectroscopy studies. The thermoregulatory and other physiological changes that a human subject displays in response to exposure to rf radiation are dependent on the amount of energy that is

Figure 2 The signal-to-noise ratio increases with frequency linearly up to about 80 MHz (about 2 T). Theoretical predictions show that, for the human head, there will be quadratic dependence between the signal-to-noise ratio and frequency above 80 MHz

absorbed and the rate at which this energy is distributed in the body and released to the environment.

Several studies of volunteer subjects and patients undergoing clinical MR procedures have derived information that would be applicable to the patient population typically encountered in the MR setting.^{43–45} The whole-body-averaged SAR values ranged from approximately 0.05 W kg^{-1} (for MR procedures involving imaging with a transmit/receive head coil) to 4.0 W kg^{-1} (for MR procedures involving the imaging of the spine or abdomen with a transmit/receive body coil). These studies demonstrated that changes in body temperatures were relatively minor (less than 0.6°C). Skin temperatures increased by as much as 4°C , but this increase reached an asymptote after 30 min as the body lost heat through Joule–Thompson cooling. There were no associated deleterious alterations in any of the hemodynamic parameters that were assessed during these investigations (heart rate, blood pressure, and cutaneous blood flow).⁴⁶

Figure 3 The maximum locus specific absorption rate (SAR_L) and the SAR are plotted versus frequency for a 20 cm diameter sphere with appropriate frequency-dependent conductivity and dielectric properties. The data are for a 12 cm diameter coil displaced 2 cm from the sphere. The rf for these studies was a $75 \mu\text{s}$ pulse with a repetition every 400 ms and with an amplitude to give a 35° tip in a volume element 5 cm into a sphere

As the operating frequency is increased, tissue conductivity increases, resulting in a higher ionic current and consequently a higher SAR. Higher tissue conductivity also means weaker B_1 field penetration, and higher rf power is needed to achieve the same B_1 field strength (the same flip angle) at a given spatial location as obtained at a lower frequency. For imaging and spectroscopy at fields as high as 10 T, power deposition calculations must incorporate not only the influence of intervening tissue (skin and skull in the head, fat in the body)⁴² but also standing-wave effects; the wavelength inside brain matter is approximately 10 cm at 430 MHz.

5 CONTRAST AGENTS

The major contrast agent for MRI studies is a gadolinium chelate (gadopentatate dimeglumine), which is injected at a dose of 0.1 mmol kg^{-1} body weight. The largest study of adverse reactions completed in 1995 included 15 496 patients.⁴⁷ Adverse reactions occurred in 2.4% of patients. Only two patients had serious, but not fatal, adverse reactions and these were thought to be caused by interaction of the underlying disease with the contrast agent. Contrast studies have been done in all age groups and it does not appear that the use of contrast agents represents a hazard even to children younger than 2 years of age. Other contrast agents include $0.1 \text{ }\mu\text{m}$ magnetite particles in various adjuvants, magnesium in chelate forms, and gadolinium attached to proteins such as albumin. The last has also been found to be a safe imaging agent for the vascular system.

6 IMPLANTS

MRI procedures might be performed on patients with temporary or permanent ferromagnetic objects in the body. There are five types of permanent implant (metallic foreign bodies, metal plates, prostheses, surgical clips, and cardiac valves), a number of different semi-permanent devices (pacemakers, hearing aids, cerebrospinal fluid shunts), and temporary devices (e.g., therapeutic instruments, esophageal pacers, stereotaxic surgery frames, cervical fixation devices). The hazards of metallic foreign bodies, particularly those associated with the eye, surgical clips, and pacemakers, have been extensively studied.⁴⁸

Three potential hazards are associated with pacemakers.⁴⁹ One or more of the interactions of the physical components of the MR exposure (static magnetic fields, time-varying magnetic fields, and rf exposure) may cause an effect. Synchronous pacemakers have a special sensing circuit that analyzes incoming electrical activity and initiates a pulse to pace the heart only if the actual heart rate slows. Modern pacemakers are programmable and output voltage, current, pulse width, and rate can be determined and altered noninvasively.

When a patient with a demand pacemaker is examined, a hand-held magnet (approx. 0.1 T) is used to close a reed switch, thereby bypassing the pacemaker sensing system and converting the pacemaker to asynchronous operation. Demand pacemakers entering the magnetic field of a MRI unit will revert to asynchronous operation as a result of the reed switch being closed. If a demand pacemaker does not have a functioning reed switch, electromagnetic interference can fool the circuitry into thinking

appropriate electrical activity is present. These false signals are generated because the pacemaker lead is an antenna that is susceptible to electromagnetic environments. The numerous ferromagnetic components within a cardiac pacemaker will exhibit a force of attraction and torque in a magnetic field. A torque will be experienced as the pacemaker attempts to align itself properly along the magnetic lines of the field. Most of the actual tests done with patients having pacemakers were at 0.35 and 0.5 T. These tests have not reported disturbances when systems are tested in the asynchronous mode.

The induced current for a cardiac pace catheter are below the cardiac stimulation threshold, which is 5 A m^{-2} . However, tissues surrounding wires that act as antennae can be heated through E field induction from the local magnetic field associated with the currents in the conductor.

The dangers associated with implanted surgical clips result from translational forces, or torque, between the magnetic material in the clip and external magnetic field. The earliest quantitative studies of forces on surgical clips were in 1983.⁵⁰ Some clips, while not considered ferromagnetic by the manufacturer, can have magnetism induced in the manufacturing processes. Criteria for testing clips have been established wherein displacement and rotation thresholds are set at 0.15 T m^{-1} and 0.15 T, respectively, and an extensive catalog of test results has been compiled.⁵¹⁻⁵⁴ For example type 316L stainless steel is nonmagnetic but type 301 or 17-7 (P)M stainless steel is magnetic. The potential of twisting or displacement is dependent on how well the clip is imbedded in the surrounding tissue. Dental stainless steel (type 316) for orthodontics is magnetic and causes artefacts, but the hazard of dislodgment is minimal.

Cardiac valves in patients do not preclude MRI examinations. Field distortions associated with some ferromagnetism might preclude imaging but in general these valves will not be twisted or rendered nonfunctional at 1.5 T.⁵⁵

Cerebrospinal fluid shunts are frequently used in patients with brain disorders who require MRI studies (e.g., with hydrocephalus). These metallic devices cause less artefacts in MRI than in computed tomography. The deflection forces at 1.5 T can be as much as 0.02 N .⁵⁶ Cervical fixation devices and stereotaxis frames have also been studied; if these are made of nonferromagnetic material they are compatible with MRI.⁵⁷

7 CONCLUSIONS AND GUIDELINES

In 1997, the American Food and Drug Administration revised the guidelines from 1982 regarding the assessment of risk in proposed clinical studies of investigational MR devices.⁵⁸ These guidelines are: (i) the limit of the static magnetic field is 4 T (but the Institutional Review Board can approve studies beyond 4 T); (ii) SAR is limited to 4 W kg^{-1} averaged over the whole body for any period of 15 min, 3 W kg^{-1} averaged over the head for any period of 10 min, and 8 W kg^{-1} in any gram of tissue in the head or torso or 12 W kg^{-1} in any gram of tissue in the extremities for any period of 5 min; (iii) dB/dt is limited to levels that will avoid 'severe discomfort or painful nerve stimulation'; and (iv) peak unweighted sound pressure level limit is 140 dB or an A-weighted root-mean-square sound pressure level greater than 99 dBA with hearing protection in place.

The static fields now considered safe are 8 T and beyond. The switched fields used at many installations today are 50 T s⁻¹. The whole body SAR of 4 W kg⁻¹ or more is needed if the core temperature elevation of 1°C is the criterion, though earlier work with rf did show operant behavior changes in sub-human primates at 4 W kg⁻¹. The 0.4 W kg⁻¹ as a whole body guideline for rf remains a prudent guideline from the IEEE (Institute of Electrical and Electronics Engineers) Standards Board. The partial body guideline of 8 W kg⁻¹ will not result in a 1°C temperature change for organs with blood flow of 1 ml min⁻¹ 100 g⁻¹. Records of MRI operations have been without serious incident other than the avoidable incidents of burns from external wires near the patient, projectiles entering the magnet space, or ferromagnetic foreign objects imbedded near vital organs. As the magnet designs of the near future are changing and MRI is being used for new applications such as minimally invasive surgery, continuing surveillance of the potential hazards is needed.

Patient Life Support and Monitoring Facilities for Whole Body MRI

Chris Boesch

University of Bern, Switzerland

1 INTRODUCTION

'Patient life support and monitoring' is a subject that arises with MRI examinations within whole body magnets of patients experiencing unstable vital functions. It includes any type of method, device or activity employed to survey or to maintain the vital functions of a patient undergoing an MRI examination.

1.1 Overview

Patient monitoring and care during magnetic resonance (MR) examinations is a subject that combines principles from very diverse fields of applied engineering, electronics, and MR physics, with medical considerations of patient care and intervention.^{1–19} The MR system environment is, in general, incompatible with standard hospital life support and monitoring devices due to strong electromagnetic interactions between the equipment and the MR system, affecting both. An estimate of the magnitude of the interactions involved is dramatically illustrated by the following example: while the MR system generates rf pulses of several kilowatts power and of a few milliseconds duration within the whole body coil, patient electrocardiogram (ECG) monitoring requires the registration of electrical signals from the patient's heart with a magnitude of several millivolts. This incompatibility problem is compounded by the fact that the patient is hidden from view during the relatively long time period of the MR examination.

1.2 Historical Perspective

In the past, many high-risk patients (i.e. those with unstable vital functions) have either been excluded from vital MRI studies, or have been examined with insufficient monitoring and care, since MR-compatible monitors and life support devices were unavailable. In the early years of widespread MR use, MR sites had individually to seek monitoring solutions for select patients and for certain affected instruments.^{1–17} Many designs for monitoring solutions appeared in the literature; however, some were not generally applicable or were impractical for routine MR examinations (e.g. locating an anesthesia ventilator 10 m from the patient). Because of the lack of commercial MR-compatible devices and the lack of technical understanding of the many concepts involved, government regulations and device approvals in many countries have lagged behind the diagnostic success of MRI.

2 MEDICAL CONCEPTS: BACKGROUND

Medical management of a patient confined within the restrictive magnet bore differs considerably from that of a surgical patient or one monitored in the ward where there is complete accessibility. Patient monitoring should also not be confused with the detection of the patient's heart rate for MR pulse sequence triggering purposes only. Monitoring and life support during MRI examinations requires adapting some basic concepts to the medical needs specific to a patient group. For example, a healthy but sedated child requires much less monitoring and treatment compared to an unstable patient from the intensive care unit (ICU).

2.1 Relevant Patient Categories

The diagnostic power of MRI has led to an increasingly larger number of examinations involving high-risk patients, who necessarily may require treatment and monitoring during an MRI scan. These include, for example: anxious²⁰ or uncooperative patients (e.g. children, and patients in a confused state) who need to be examined under sedation^{21–24} or anesthesia because of their illness or lack of cooperation; critically ill patients from the ICU (e.g. patients with acute craniocerebral trauma,¹⁴ spinal cord injury,^{25,26} or myocardial infarction¹⁵), especially those who are intubated and artificially ventilated, require optimal life support; and premature infants,^{5,12} who need a controlled atmosphere within an incubator^{12,27–30} and require dedicated equipment due to smaller volumes.¹⁶

Even MRI examinations of completely stable patients or outpatients may require monitoring.²² In particular, sedated patients being examined in the supine position can vomit, leading to potentially life-threatening situations (aspiration and airway obstruction). MR guided medical interventions will increase the number of patients who absolutely require continuous vital function monitoring.

2.2 Monitoring Functions

In addition to verbal contact with the patient (if possible), three general categories of physiological functions of the human body are monitored:^{2–4,11–13,18,19} cardiovascular parameters, respiratory parameters, and body temperature. Table 1 summarizes these and the vital functions which they indicate.

ECG records electrical potentials at the body surface generated by the activity of the heart. An ECG gives an immediate measure of heart activity, unlike observation of the pulse in the periphery which is delayed by the finite speed of the pulse wave. In addition, the ECG contains slowly varying components which are a consequence of body impedance changes during respiration. These components can be used to evaluate respiration rate by 'impedance plethysmography'. The cardiovascular system can be assessed by pulse oximetry, skin blood flow, and noninvasive or invasive blood pressure (NIBP and IBP). Pulse oximetry exploits the effect that binding of oxygen to hemoglobin in erythrocytes changes the absorption spectrum. Absorption of light at two different wavelengths, red and infrared, by the tissue (e.g. finger, toe, or neonate foot) allows the determination of both the oxygen saturation of the blood and

Table 1 List of Vital Physiological Parameters

Physiological parameter	Observed vital function
Electrocardiogram (ECG)	Electrical heart action
Pulse oximetry (SaO ₂)	Cardiovascular (peripheral pulse) Oxygenation (blood saturation)
Temperature	Body or skin temperature
Noninvasive blood pressure (NIBP)	Cardiovascular (blood pressure)
Invasive blood pressure (IBP)	Cardiovascular (blood pressure)
Capnography	Respiration frequency End-tidal CO ₂ /NO ₂
Inspired O ₂ , anesthesia gases	Mixture of breathing air
Transcutaneous pO ₂ , pCO ₂ (neonates)	Partial pressure of O ₂ and CO ₂
Impedance plethysmography	Respiration rate
Skin blood flow	Peripheral perfusion

the pulse rate. In infants, transcutaneous estimation of oxygen and carbon dioxide partial pressure is possible, but is not widely used during MR examinations. Cutaneous blood flow can be assessed by the Doppler effect of light which is reflected by moving blood cells. The NIBP determination measures systemic blood pressure by the inflation of a cuff around an extremity; the blood flow in the extremity is compared with the pressure applied by the cuff. In the IBP determination the pressure from within the vascular system is transmitted by an inserted tube to a pressure transducer outside of the magnet bore. Capnography analyzes the absorption of infrared light by the expired air in a chamber located outside of the magnet bore. In an intubated patient with a closed ventilation circuit, capnography determines respiratory rate, absolute concentrations of end-expiratory CO₂ and of some anesthetic gases. In a nonintubated patient, absolute concentrations cannot be measured by capnography, but the respiratory rate can be measured by using a sampling tube in the airflow (e.g. in the nose). During mechanical ventilation, anesthetic gas and O₂ concentrations in the inspired air flowing through the ventilator can be analyzed.

2.3 MR Scanning Room and Monitor Setup

Figure 1 shows a typical MRI suite with monitoring and life support devices. At most sites, the MR scanning room has a wall-integrated Faraday shield, and the door (as part of the shield) must be closed during scanning. Environmental rf noise is attenuated by 100 dB, typically, by the Faraday-shielding, leaving the magnet room almost rf noise free. Residual rf noise would be additionally attenuated by the inherent Faraday shielding effect of the magnet bore. Potential sources of rf noise inside the magnet room, including patient monitoring devices, must be shielded carefully.

2.4 Patient Accessibility and Visibility in the Magnet

During an MR examination in a classically designed cylindrical bore whole body magnet, the patient lies in a tube that is

2 to 3 m long and approximately 60–70 cm in diameter, which is relatively narrow for an average adult. The patient is only partially visible and accessible by the medical staff. In patient surveillance on the ward, direct staff contact with the patient and inspection of his or her respiration, skin color, heart action, and body temperature are important monitoring factors. During an MRI examination (typically 20–60 min long) this contact is severely restricted. Even use of a stethoscope is limited by the loud noise of the switched magnetic field gradients. Therefore, technical monitoring devices are needed to provide the necessary patient physiological information.

The inaccessible patient cannot be treated without special preparations. Arrest of bleeding or emergency treatment are not generally possible while the patient is in the magnet bore. Infusions and intubation must be prepared outside the magnet bore, prior to the MRI examination, with tubing of appropriate longer length. Replacement of misplaced or detached sensors is usually not possible without interruption of the MRI examination. Fortunately, MR examinations have the feature that they typically can be interrupted, unlike a surgical intervention which must be finished regardless of unexpected events. New advanced MR methods introduce elements of classical surgery into MRI, and interventions under MR control thus need to be continued without interruption or delay.

Figure 1 Schematic arrangement of an MRI site with monitoring devices. The magnet with the patient is located inside a Faraday-shielded room which is completed with a shielded door, that must remain closed during scanning. The inner part of the Faraday-shielded room is intended to be free from any rf noise. Thus, all additional devices inside the room have to be carefully rf shielded and all connections between the inside and the outside have to go through a filter panel. Three different monitoring and life support systems are indicated: (1) single components such as ventilators or single-parameter devices; (2) a complete integrated monitoring system; (3) a complete modular monitoring system. (2) and (3) both have (simplified) connection boxes (a), one or more monitors (b), and satellite devices at the console (c)

2.5 Monitoring Scenarios and Staff

During most MR examinations the Faraday shielded magnet room door must be closed, and thus the monitoring staff cannot enter or exit freely. This barrier distinguishes two different approaches to monitoring: surveillance by one responsible staff member located adjacent to the patient inside the magnet room, and complete remote monitoring from outside the magnet room. As either approach could be appropriate for a specific patient, control and display devices of the monitoring system should be available at different locations inside and outside the magnet room.

Stable outpatients are often monitored by use of displays outside the MR room, in some cases by the MR technicians, who are simultaneously operating the MR system. Notably, with mild patient sedation there is a chance of vomiting, requiring immediate action to prevent aspiration. This response can be delayed by a technician who is also responsible for the MR image acquisition.

Any instability of the patient's vital functions, including administration of common doses of sedatives, requires that one medical staff member be responsible for monitoring and intervention²² and remains in the magnet room with the patient. This staff member must have available a display of all monitoring parameters, and be able to modify the sensing and display of the measured parameters (e.g. ECG derivation and amplification). Depending on the specific patient, this staff member can either be an anesthesiologist, a pediatrician or another specialist.

2.6 Triggering vs Monitoring

The terms 'triggering' and 'monitoring' are often confused. Most MR manufacturers provide an ECG recording sensor for triggering, i.e. the temporal coordination of MR pulse sequences with the heart action. These sensors can also be used for patient monitoring between MR scans. However, for monitoring purposes during MR examinations, the ECG needs to be recorded and displayed continuously without any degradation, and without any treatment which could suppress physiologically important features of the ECG. Supplied ECG sensors for triggering are often neither continuous nor undistorted. Severe distortion of the ECG, blanking of preamplifiers governed by the acquisition sequence, strict filtering, or post-processing of the ECG signal can suppress signals from the heart which would indicate a malfunction, or mimic heart function failure.

3 PHYSICAL PRINCIPLES OF INTERACTIONS: BACKGROUND

During a MRI examination, various electromagnetic fields are generated by the MR system and monitoring and life support devices. Each of these fields can be the basis of mutual interactions between the different devices and/or the patient.³¹ For a description of an MRI acquisition, see also *Image Formation Methods; Gradient Coil Systems*. For effects of the various fields on the patient, see also *Radiofrequency Systems*

and Coils for MRI and MRS and *Health and Safety Aspects of Human MR Studies*.

3.1 Applied Physical Principles

The interactions that can occur between the MR system and monitoring devices can be described in terms of several physical principles:

1. Mechanical forces and a distortion of the magnetic field occur when ferromagnetic material is within a static magnetic field.
2. Faraday's law describing electromagnetic induction states that a temporal change in the magnetic flux (defined as the product of a magnetic field and the penetrated area) induces an electrical voltage in a conductor surrounding the penetrated area. Thus both a changing magnetic field (switched gradients, rf) and variations in the area (moving body, wires) generate induced voltages.
3. The 'Lorentz force' is experienced by electrical particles [e.g. electrons in a cathode ray tube (CRT), or ions in blood] moving in a magnetic field, with this force being perpendicular to both the path of the particle and to the magnetic field direction.³¹

These different physical principles are applied below to explain a number of interactions (Figure 2).

3.2 Static Magnetic Field

The static magnetic field (typically 0.2–2 T for whole body MR systems) is always present, having a very homogeneous region inside the magnet bore and decaying within several meters outside the magnet bore (i.e. the fringe field). The most well-known characteristics of a static magnetic field are the attractive force and torque it exerts on ferromagnetic objects, the effects of which depend on the size and shape of the

Figure 2 Synopsis of possible interactions between an MR system, monitoring devices and life support systems, the patient, and the environment. CRT, cathode ray tube

Figure 3 Examples of interactions between an MR system and monitoring devices. (a) ECG recording before and during an MRI sequence. The sharp spike is called the QRS complex; it is followed by the smooth T-wave, which is elevated by the static magnetic field.³² (b) A rf emission from an unshielded monitor causes artifacts in an MR image (horizontal stripes). (c) A tilted trace on the CRT screen of an ECG monitor located several meters away from the magnet

object. The largest attraction is experienced in a highly inhomogeneous static field, which in the case of MRI is at the opening of the magnet. Valves, relays, etc., can be influenced by the static field, and CRT displays are distorted even at a distance of several meters from the magnet (Figure 3). Ions in blood flowing in the static magnetic field experience the Lorentz force, which generates voltages that distort ECG registration.³² This effect elevates the T-wave of an ECG reversibly (Figure 3) such that its diagnostic value is limited to an observation of cardiac rate and rhythm; it cannot be used to determine an ischemic heart attack, for example.

Based on the Faraday law, any motion of a part of the body in the magnetic field induces electrical potentials. These electrical potentials seem to be harmless, but nevertheless can interfere with electrical physiological measurements such as an ECG recording. Depending on the size and location of ferromagnetic objects relative to the magnet, the static magnetic field can be distorted by the induced magnetic field. The resulting inhomogeneity in the region of interest can, in particular, impair MR spectroscopy, although the forces experienced by the ferromagnetic object are usually the more pronounced problem.

3.3 Switched Gradients and Diode Currents

Time and spatially varying gradients (typically around 10 mT m^{-1}) are switched in fractions of milliseconds on MR systems. (New equipment has maximum slew rates of approximately $250 \text{ mT m}^{-1} \text{ ms}^{-1}$.) Diode currents are switched in fractions of a millisecond and are used to change detection and excitation coils from the resonant to a nonresonant mode.

Switched gradients are a source of audio noise and induced potentials in conducting objects, as explained by the Faraday

law. The audio noise is a direct consequence of the mechanical force experienced by the gradient coils when the current producing the gradient fields is flowing in the main field (Lorentz' law). Voltages induced by the gradients are picked up in loops formed by wires in the magnet such as the ECG electrodes.

3.4 Radiofrequency Fields

Strong rf fields at the resonance frequency of the MR system (usually between 10 and 100 MHz for whole body systems) are generated for the excitation of the spins in specially tuned and shaped coils, driven by transmitters of up to 20 kW. These strong rf fields are the basis for very complicated, rarely reproducible, yet important interactions. Radiofrequency induced voltages in other devices cause distortion of electrical measurements, saturation of preamplifiers, or even the destruction of electronic circuits. Even with high-resistance carbon ECG electrodes, moderate warming of the skin has been observed under test conditions.

An additional and important effect of rf interference has been observed in situations lacking any direct galvanic contact between a patient's skin and the conducting wires. Each conducting wire represents an inductance and can—in connection with the capacitance-like structure which exists in every loop of a cable—form a resonant circuit. This can be excited by the electromagnetic field and subsequently focus considerably high electromagnetic field strength within small distances (less than 5 mm) around the wire. Thus, hazards of burning (up to third degree, requiring surgical skin grafting) have been reported in connection with pulse oximeters.^{33,34} These interactions are not limited to direct (galvanic) contact with the patient or to cases of destroyed sensors, but can occur with any conducting structure of low resistance. Since the wiring arrangement affects the resonance behavior, these effects are rarely reproducible.

Modern patient monitors may contain a large amount of digital electronics having rf emissions of frequencies up to several megahertz; these typically cause image artifacts (Figure 3).

The intrinsic Faraday-shielding property of a magnet bore can be reduced by the presence of electrically conducting structures entering the magnet, e.g. an ECG cable. This effect can lead to puzzling observations. A wireless non-rf-shielded device (e.g. a NIBP monitoring device with plastic tubes) can work successfully without causing MR image degradation. However, when other devices such as an ECG are introduced alongside, image artifacts can appear, leading to the incorrect assumption that the additional device (i.e. the ECG) is the source of rf noise. Actually, the wires of the additional device were used as a guide for the rf noise from the electronics of the first device outside the magnet bore to circumvent the rf shielding effect of the magnet tube. Similarly, rf from the environment, if not attenuated by the wall-integrated Faraday-shield of the MR suite, can use monitoring wires to bypass the Faraday-shielding effect of the magnet bore.

3.5 MR Sequence Timing and Differentiation of Interactions

During an MRI sequence, different physical forces act simultaneously (Figure 4). Motion in the static magnetic field,

Figure 4 Schematic representation of a simplified MRI sequence (one phase step of a conventional spin echo sequence with a typical timescale) with different physical effects acting as possible sources of interactions with patient monitoring. Shaded lines indicate the generation of voltages in conducting structures by changing electromagnetic fields

switched gradients, diode currents, and rf pulses generate voltages in electrically conducting structures such as wires and the patient's body. These electromagnetic fields are switched (i.e. pulsed) several times within a few milliseconds and are indistinguishable to a human observer. Only interactions with the static field which are not synchronous with the acquisition are identified easily. To determine unambiguously the source of a particular electromagnetic interaction it is necessary to program the MR system such that only one of the electromagnetic fields (rf, gradients, diode currents) is generated at a time.

4 REDUCTION OF INTERACTIONS

Interactions between the MR system and monitoring and life support devices can be reduced by several different means depending on the physical nature of the interaction.^{10–13,16–19,26–30,35–44} In general, a reduction of an undesirable interaction is preferable to postcorrection of the effects. For example, a reduced pick-up of voltages in the registration of the ECG is superior to filtering the distorted signal.

4.1 Monitoring vs Life Support Devices

Experience has shown that it is much more difficult, in general, to modify patient monitoring devices for MR compatibility than it is to modify life support equipment, especially mechanical ventilation units.^{4,7,8,11,13,16–19} For hygiene reasons, most life support devices are constructed from inert, anticorrosive material such as stainless steel. This material is, conveniently, mostly nonmagnetic. Monitoring devices, on the other hand, usually contain many more electronic components, especially digital circuits, which interfere with the MR system.

4.2 Static Magnetic Field Effects and Use of Nonmagnetic Material

If possible, all ferromagnetic parts (valves, batteries, screws, boxes) of monitoring devices should be replaced with nonmagnetic components. The inevitable remaining ferromagnetic parts of equipment (e.g. the motors of the blood pressure cuff, transformers) should be located as far as possible from the magnet in order to reduce attraction and malfunction. CRT screens or oscilloscopes used near the magnet can be replaced by liquid crystal or plasma displays. Magnetic shielding and rotation of the CRT display deflection unit is only successful at a certain distance from the magnet. MR examinations using magnetic field strengths below 0.3 T are less problematic^{14,25} than high-field MR systems because of the weaker fringe field and the large bore size of the magnets.

4.3 Radiofrequency Effects and Shielding

Radiofrequency interference can arise both from rf emissions originating from the monitor and interfering with the MR system, and from the strong rf pulses of the MR system rf coil and detected by the monitoring equipment sensors. Faraday shields surrounding electronic devices and high grade low pass filters can stop the emission and detection of rf. Some sensors (e.g. in pulse oximetry), however, require well-defined signals at higher frequencies (for the definition of the edges of signals), thus limiting the use of low pass filters. Reduction of rf interference from the environment is generally achieved by a wall-integrated Faraday shield (Figure 1), thus keeping the magnet room free from ambient rf noise. One manufacturer has utilized the inherent Faraday shielding effect of the magnet bore in its system design, by the use of an additional cylindrical tube which represents an elongation of the magnet bore.¹⁷ This scheme requires different monitoring approaches and is not considered here.

MRI should be considered as a very sensitive experiment done over an extremely narrow frequency bandwidth. Even military-grade rf test sites are less sensitive than is necessary for MR system interference testing. Rf interactions and interference depend largely on the actual resonance frequency (i.e. field strength) of the MR system, the arrangement of the emitter, wires, the patient, the rf coils, and the imaging sequence. Therefore, the rf interactions that affect equipment are rarely reproducible. Only very careful design of filters, a large number and variety of tests, and use of nonelectrical measurements (see below) guarantees successful prevention of electromagnetic interactions.

In order to reduce the risk of burns caused by wires forming a resonant structure, MR manufacturers usually request that no loops and no direct contacts between the patient and any electrically conducting material are made.^{18,19} ECG recording, however, inherently requires a galvanic (i.e. direct electrical current) contact with the patient. Burn hazards associated with ECG electrodes are reduced by using carbon electrodes with an increased specific electrical resistance.³⁵

4.4 Magnetic Field Gradient Effects

According to the Faraday law, reducing the area surrounded by conducting wires has the effect of decreasing induced po-

Figure 5 Two examples of MR compatible monitoring systems, both with a complete set of observable vital parameters (e.g. ECG, pulse oximetry, NIBP, end-tidal CO₂ and O₂, impedance plethysmography, temperature, IBP). Both systems have an additional data display on a slave monitor in the MR console operator room. [Reproduced by permission of In Vivo Research (bottom) and ODAM-Bruker (top)]

tentials. This principle should be utilized whenever possible. For example, an appropriate positioning of ECG electrodes and twisting of the cables can considerably reduce artifacts on the ECG recording.^{10,12,36}

Low pass filters,³⁷ blanking of the preamplifier, postprocessing or other methods can efficiently eliminate spikes from an ECG trace due to pulsed MR magnetic field gradients. However, since monitoring needs a continuous, clean ECG, some of these methods are limited to triggering purposes, as mentioned above.

4.5 Location of Monitoring Equipment

In the past, many MR sites used MR-incompatible monitors located outside the magnet room. This separation of monitors and MR system (including the patient) in two different rooms can solve the strong interaction problems, but it also introduces new problems. First, it requires wires and tubes that are too long. Also, two members of the medical team are necessary, one observing the monitors and describing his or her impressions to the other who is examining and, if necessary,

treating the patient. This can cause misunderstandings and delays between the first observation of irregularities and an intervention.

4.6 Use of Optical, Mechanical, and Pneumatic Devices

Whenever possible, optical or mechanical means instead of electrical recording should be used for monitoring devices in order to avoid electromagnetic interferences.^{38–44} In recent MR compatible pulse oximeters, the light source and detector are located outside the magnet and coupled to a fiber optic cable leading to the patient.^{19,42} Temperature can be measured by means of optical sensors.⁴³ An ECG monitor, which amplifies and transforms the electrical signal to an optical light directly on the patient,⁴⁴ avoids interference by using a miniature pre-amplifier box and only optical fibers. NIBP measurement is inherently mechanical; here, pressure variations in an overly long tube can cause problems with accurate detection. Long sampling tubes can also affect detection by causing a delay in the remote analysis of breathing gases (capnography). Also, mixing of gases flowing through a long tube averages the gas content readings. For IBP measurement, the pressure transducer can be located outside the magnet bore, connected to the patient with a long plastic tube (e.g. two infusion sets in series).

5 STATE OF THE ART

The present state of patient monitoring during MRI examinations includes a heterogeneous mix of commercially available, home built, and MR incompatible systems. Several complete systems (Figure 5) and various single purpose instruments¹⁹ are commercially available.

5.1 Medical Needs of Different Patient Categories

Table 2 summarizes the frequently used combinations of parameters and life support for patients with different levels of medical needs. It can be seen that very different levels of

Table 2 Use of Vital Parameters for Determining the Status of Different Patients^a

Patient condition	Examples of observed parameters and life support
Stable cooperative patient	ECG (for triggering)
Sedated stable patient	ECG, pulse oximetry
Premature baby	ECG, pulse oximetry, capnography (respiration frequency), temperature, incubator
Intubated, ventilated patient	ECG, pulse oximetry, capnography, temperature, NIBP/IBP, ventilator, inspired O ₂ , anesthesia gases, infusion sets, intubation, emergency equipment

^aThis table represents typical cases and is meant to be an illustration. In practice every case has to be considered individually by the staff responsible, taking into account the medical history of the patient and the guidelines of the corresponding professional association.

monitoring equipment are required for different patient categories. Each patient must be considered individually by the staff responsible. It is important that an MR site is equipped such that all patient categories examined at that site can be monitored safely. For example, a private hospital which exclusively examines outpatients with stable vital functions can be equipped appropriately with only an MR compatible pulse oximeter. The MR department of a large hospital with ICU patients and/or premature infants requires a complete set of MR compatible monitoring and life support devices, a set of MR compatible medical instruments, and, most importantly, well trained staff following strict regulations.

5.2 Monitoring Systems

Approximately a dozen MR compatible single components used mainly for monitoring heart rate, oxygen saturation, peripheral pulse, and respiratory rate are available that can provide surveillance of stable patients in the manner in which they are commonly examined in nonhospital MR sites.^{18,19} For hospital needs, however, where some patients require a higher level of surveillance, only a few complete monitoring systems are commercially available (see e.g. Figure 5). When using an assortment of single devices to provide comprehensive monitoring, the interactions between the different equipments and their mutual compatibility (including user interface, location of the equipment, length of tubes and cables, power connections) need to be considered prior to purchase.

5.3 Ventilators

Various MR compatible ventilators are manufactured and available commercially.^{18,19} However, since anesthesia equipment is heavily regulated by local authorities (following often very traditional local rules), not all commercial systems are approved in all countries.

5.4 Incubators

MR compatible incubators need to satisfy the spatial restrictions within the magnet, and to prevent interactions between the accompanying heater/ventilator apparatus and the MR system. Some incubators used for research studies have apparently solved these technical problems,^{12,27–30} but governmental regulations and the limited market seems to inhibit the approval of these as commercial products.

5.5 Medical Instruments

MR compatible nonmagnetic medical instruments (infusion sets, laryngoscope, intubation material, lamps, scissors, stethoscope, clamps) are commercially available.¹³ The supply of MR compatible medical instruments is only one aspect of their usage in the MR environment. Since these devices sometimes look identical to their MR incompatible magnetic counterparts, it is very important to separate MR compatible from ferromagnetic instruments by strict rules. In some cases, only invisible inserts make the difference, for example a nonmagnetic laryngoscope can contain highly ferromagnetic batteries.⁶ As a rule, all devices and instruments in an MR site should be MR compatible, including those which are used only in the preparation

room. Emergency carts are specially prone to causing accidents, since they are used in hectic situations with reduced attention to the hazards of the strong magnetic field of the MR system.

5.6 Patient Positioning Aids

While most MR system manufacturers provide MR compatible positioning aids, such as coil holders for the different organs of an adult patient, only a few offer special devices for certain patients such as infants. Different approaches have been suggested and, inevitably, every MR site invents its own equipment. One commercially available solution is a vacuum mattress for the positioning and immobilization of patients, especially infants. This mattress contains small plastic spheres in an airtight bag which retains its shape after evacuation.

5.7 Accident Prevention and Training

Many MR sites still have limited experience with the MR examination of high risk patients and, generally, anesthesiologists and pediatricians are not very familiar with MR technology. Since the interactions that exist in this environment are unfamiliar, invisible, and nonintuitive, the education of radiologists, anesthesiologists, pediatricians, and technicians must include some background information on the relevant electromagnetic forces.

Technical devices have a very limited capacity to correct human errors in an MRI room. Metal detectors are available in many sites, but typically are ineffective since they detect electrical conductance and not ferromagnetism—an MR compatible stainless steel device is detected in the same way as a 20 kg iron oxygen bottle.

6 OUTLOOK

Future developments will influence patient monitoring and life support considerably. Future MR technology (e.g. magnets, sequences), new MR diagnostic procedures, the increasing number of MR sites, and governmental regulations will change many aspects.

6.1 Governmental Regulations

Due to the lack of generally accepted devices and strategies in the past, many individual solutions, some inappropriate, were arrived at and reluctantly accepted.²² Since MR-compatible monitoring devices are now available, governmental rules and guidelines of the corresponding professional association^{21,22,24} will increasingly regulate patient monitoring in different countries.

6.2 High Risk Patients and Interventional MRI

The increasing number of MR systems in use increases the possibility that MR sites will scan more high risk patients. Subsequently, new experience gained from high risk patients will increase the potential of MRI and expand its possible applications (e.g. hemorrhage, trauma). Interventional MRI will

introduce the monitoring needs typical for conventional surgery into the concerns for patient monitoring during MRI.

6.3 Magnet Technology

Magnets with efficient passive or active shielding of the fringe field are already commercially available. Mainly designed for easier placement of the magnet in a building, this innovation also helps to reduce the effect of the fringe field on monitoring systems. Recently introduced 'open magnets', e.g. as used in interventional MRI will give more access to the patient and make monitoring easier. However, the inherent rf shielding effect of long cylindrical magnets is lost in open magnets.

6.4 New MRI Sequences

Very rapid MR sequences (see e.g. *Echo-Planar Imaging*) will reduce the total time needed for an MR scan session, as well as the time taken for a single scan. This will open up a new field of applications (e.g. breath-hold images, images of the abdomen, images of arrhythmic hearts) and will allow the examination of noncooperative patients and children in a shorter period without the need for lengthy immobilization. This will increase the number of problematic patients receiving MR examinations, yet reduce monitoring problems due to the shortening of the examination time. Since electromagnetic fields are switched more quickly during examinations using these sequences, interactions with other technical devices such as monitors will increase.

6.5 Developments in Patient Monitoring

Patient monitoring itself will develop such that most parameters will be measured by optical or hydraulic/pneumatic means. Electrical measurements will be avoided whenever possible.³⁸⁻⁴⁴ Inherent electrical measurements, such as an ECG, will be altered so that the electrical component will be miniaturized.⁴⁴

6.6 Summary

Patient monitoring will have an increased importance in the future because of the increasing number of high risk patients examined and interventional MRI applications. Monitoring will be less problematic due to new technical developments in the engineering of monitoring systems and of the advancement of MR technology, including magnet design and very rapid image acquisition.

Radiofrequency Fields: Interactions, Biological Effects, and Safety Issues

Jeffrey W. Hand

Hammersmith Hospital, London, UK

1 INTRODUCTION

The term radiofrequency (rf) is often used in the biological effects and occupational health literature to cover the frequency range from 300 kHz to 300 GHz. Sometimes there is additional discrimination within this range in that use of the term rf is restricted to frequencies up to 300 MHz while the higher frequencies are referred to as microwaves. Radiofrequency fields and radiation differ from ionizing radiation in that the photon energy, given by the product of the frequency and Planck's constant, is much smaller than the 12.4 eV required for ionization. In MR applications, the frequency of the B_1 field usually matches the Larmor precession frequency ν , which is related to the static magnetic field B_0 as in Equation (1)

$$\gamma B_0 = \nu \quad (1)$$

where γ is gyromagnetic ratio. The value of γ is 42.57 MHz T^{-1} for the hydrogen atom and so the B_1 field frequency for typical clinical MR systems (with B_0 of 0.2–2 T) lies in the range 8.5–85.14 MHz. Higher frequencies, up to about 400 MHz, are encountered in high B_0 MR systems used for research. Typically, rf energy is applied as a series of pulses with duration ranging from 10 s of microsecond pulses to 10 s of millisecond pulses depending upon the MR application.

Traditionally, the consensus of scientific opinion is that interactions between rf fields and the human body are considered to be thermal, although there have been claims for other mechanisms of interaction. The energy absorbed is directly related to the rf fields inside the body and not those incident upon the body. The internal and incident rf fields can be quite different, depending on the size and shape of the body, its electrical properties, its orientation with respect to the incident rf field, and the frequency of the incident field. However, since direct measurement of the incident field is easier and more practical than measurement of the internal fields, especially in people, dosimetry is used to relate the internal fields to the incident field.

Much effort has been applied to understanding the interaction of rf fields with biological tissues and the associated dosimetry since the 1960s, resulting in effective procedures that minimize rf field exposure of the general public and as an occupational consequence.^{1–3} However, there are also therapeutic applications of rf fields such as diathermy and hyperthermia in which the patient is purposely exposed to high-level fields with the intention of raising tissue temperature, and a considerable body of knowledge regarding thermal responses in patients has been accrued.⁴ The evidence for harmful biological effects associated with exposure to rf radi-

ation at field intensities lower than those that produce significant and measurable heating is less clear.³

Several studies have investigated the thermal responses of humans undergoing MR examinations⁵ and safety guidelines associated with rf fields in MR have been produced. However, the dissemination of advanced MR techniques such as sequences that enable data to be acquired rapidly, the use of coils with close coupled designs and local transmit systems, the increasing availability of high B_0 field systems, and the development of interventional techniques is making realistic assessment of rf power deposition and its consequences increasingly important.

2 INTERACTIONS BETWEEN rf FIELDS AND TISSUES

2.1 Dielectric Properties

For essentially nonmagnetic media such as tissues, interaction with an rf field is predominantly through the electric (E) field, or the E field, induced in the tissue by the B_1 field and involves polarization of charges, orientation of molecules such as water and proteins that possess permanent electric dipoles, and a drift of conduction charges. In MR applications, the interaction is primarily caused by magnetic induction, with a negligible contribution directly from the incident E field. Exceptions are when tissue is placed close to feed points of transmit coils or other regions with locally high E fields, when capacitive coupling may occur.

Conduction and polarization effects are both taken into account in the quantity ϵ , known as the complex permittivity of the material and defined as:

$$\epsilon = \epsilon_0(\epsilon' - i\epsilon'') \quad (2)$$

where ϵ_0 is the permittivity of free space (8.854×10^{-12} F m^{-1}) and $(\epsilon' - i\epsilon'')$ is the relative permittivity. The dielectric constant, ϵ' , accounts for the additional polarization charge and ϵ'' , the loss factor, is a measure of how much power is absorbed from the rf field. Equation (3) shows the relationship between ϵ'' , conductivity σ , and angular frequency of the field ω .

$$\epsilon'' = \frac{\sigma}{\omega\epsilon_0} \quad (3)$$

The term σ takes account of not only the conductivity arising predominantly from mobile charges but also a frequency-dependent part arising from dielectric polarization. Both ϵ' and ϵ'' depend upon the frequency of the applied field. Radiofrequencies encountered in MR fall within the so-called β (extending from about 10 kHz to 100 MHz) and δ (extending from around 300 MHz to 1 GHz) regions of dispersion exhibited by ϵ' and ϵ'' of tissues.⁶ The β dispersion results from inhomogeneous structures including the cell membrane and intra- and extracellular fluids. At the higher frequencies within the β dispersion, and in the δ dispersion, there are contributions from the rotation of permanent dipoles (small amino acids, charged functional groups in polypeptide chains, and protein-bound water). The variation of tissue dielectric properties with frequencies may be predicted⁷ and Figures 1 and 2 show typical values for several tissues.

Figure 1 Frequency dependence of relative permittivity ϵ' for several tissues; CSF, cerebrospinal fluid

The permeability of tissues may be taken to be that of free space, $\mu_0 = 4\pi \times 10^{-7} \text{ H m}^{-1}$. The velocity of propagation is given by $1/\sqrt{(\mu\epsilon)}$ and so (see Figure 1) the wavelength associated with B_1 field in tissues of high water content is reduced by about an order of magnitude compared with that of free space at rf frequencies used in MR.

Figure 2 Frequency dependence of conductivity σ for several tissues; CSF, cerebrospinal fluid

2.2 Specific Absorption Rate

The transfer of energy from rf fields to tissue is described by the specific absorption rate (SAR), defined as the time derivative of the incremental energy (dW) absorbed by an incremental mass (dm) contained within a volume element (dV) of a density ρ .⁸

$$\text{SAR} = \frac{d}{dt} \left(\frac{dW}{dm} \right) = \frac{d}{dt} \left(\frac{dW}{\rho dV} \right) \quad (4)$$

This is the local SAR and it is related to the local internal E field through Equation (5)

$$\text{SAR} = \frac{\sigma |E|^2}{2\rho} = \frac{\omega \epsilon_0 \epsilon'' |E|^2}{2\rho} \quad (5)$$

where $|E|$ is the magnitude of the E field vector. In addition to the local SAR, spatially averaged values are also used. These are determined by dividing the time rate of change of the total energy transferred to the absorber by the appropriate mass (e.g., the total mass of the body, 1 g, 1 kg, etc.).

The importance of SAR in dosimetry arises from the fact that the absorbed energy is directly related to the internal E and B fields. These fields can be quite different from the external ones and depend on the size and shape of the body, its electrical properties, its orientation with respect to the incident fields, and the frequency of the incident fields. SAR provides measures of both the energy absorption that leads to tissue heating and the internal fields. The ability to determine the values of SAR in irradiated subjects for given exposure conditions permits meaningful extrapolation of biological effects observed in laboratory experiments to similar effects that might occur in irradiated people.

A simple estimate of the penetration of the rf field (f ; MHz) into a planar dielectrically uniform tissue is the plane wave penetration depth (skin depth) d :

$$d = \frac{1}{\sqrt{2\pi f \sqrt{\mu_0 \epsilon_0} \sqrt{\epsilon'^2 + \epsilon''^2} - \epsilon'}} = \frac{67.48}{f \sqrt{\epsilon'^2 + \epsilon''^2} - \epsilon'} \quad (\text{in meters}) \quad (6)$$

and over which the SAR is reduced to 13.5% of its original value. This attenuation leads to nonuniform rf excitation over the imaging volume. However, Equation (5) provides only qualitative understanding of realistic problems since exposure is in the near field of the transmitter coil and the body is neither planar nor dielectrically uniform. In particular, the frequency dependence of SAR exhibits resonant behavior and peak absorption occurs in an irradiated object when typical dimensions are approximately equal to half the wavelength. The value of SAR varies approximately as f^2 below resonance and as $1/f$ just beyond resonance. For appropriate polarizations, resonance occurs at around 70 MHz for the average adult whole body, above 100 MHz for a child or a neonate, and around 200 MHz for the adult head and neck.

2.3 Measurement of SAR

Two recommended methods for determining SAR in relation to rf safety of MR systems are outlined in international and national standards.^{9,10} In the 'pulse energy method', the peak power absorbed in a test object that simulates coil loading resulting from the patient, corrected for the power absorbed by the unloaded coil, is determined. The average power absorbed during the rf pulse sequence under investigation is found and the SAR is given by Equation (7).

$$\text{SAR} = \frac{1}{M} \sum_i \frac{P_{\text{object}} \int \frac{B_1(t)^2}{B_{1\text{peak}}^2} dt}{S} \quad (7)$$

where M is the mass of the test object, P_{object} is the peak power absorbed by the test object, $B_1(t)/B_{1\text{peak}}$ is the rf pulse waveform normalized to its peak value for each pulse (e.g., 90° pulses, 180° pulses) in the pulse sequence, and S is the total scan time. The 'calorimetric method' (for whole-body averaged SAR only) involves use of an annular test object containing NaCl solution that simulates the coil loading observed with 50–90 kg patients. The test object is subjected to rf pulses for a period sufficient to create a temperature increase at least 20 times the uncertainty associated with the thermometry system used.

Local SAR values greater than a few watts per kilogram may be measured within tissue-like phantoms or in vivo by determining the local change of temperature (ΔT) following a brief exposure ($\Delta t = 5\text{--}30$ s) to the fields using the relationship $\text{SAR} = c(\Delta T/\Delta t)$ where c is the specific heat (J kg^{-1}) of the medium. A nonperturbing thermometer with a resolution of 0.01–0.1°C is required. Measurements are difficult to make in regions of high SAR or when several SAR hot-spots are present (because of thermal conduction effects) and in the presence of high SAR gradients.

SAR may also be determined by measuring the internal E field with a calibrated minimally perturbing probe¹¹ and using Equation (5). The technique may be used for 10–120 MHz but can be extended to higher frequencies (hundreds of megahertz) if a suitable probe is available.

3 BIOLOGICAL EFFECTS OF rf FIELDS

The major effect of absorption of energy at frequencies above 10 MHz is heating. Increases in body temperature of more than 1–2°C may have adverse effects such as heat exhaustion and heat stroke. Exposure of resting humans to SAR in the range 1–4 W kg^{-1} for periods of about 30 min causes a change in body temperature of less than 1°C. However, the use of drugs or alcohol while a person is under thermal stress may compromise the body's thermoregulatory system. The induction of a high frequency current of about 100 mA in a limb leads to a sensation of warmth but is unlikely to result in a temperature increase of more than 1°C. Exposure of laboratory animals to E-M (electromagnetic) fields that result in SAR above 4 W kg^{-1} has been shown to result in increases in blood volume, heart rate, and blood pressure. Levels of exposure that result in changes in body temperature of more than 1–2°C may lead to changes in neural and neuromuscular functions, increase in

blood-brain barrier permeability, lens opacities and corneal abnormalities, changes in the immune system, hematological changes, reduced sperm production and motility, and teratogenicity.^{12,13}

Areas of the body that are poorly perfused (e.g., the eyes and the testes) are particularly susceptible because of their inability to dissipate an abnormal thermal load. For example, short-term exposure to rf radiation at 100–200 mW cm^{-2} can cause cataracts in experimental animals^{14,15} while temporary sterility, caused by changes in sperm count and in sperm motility, is possible after exposure of the testes to high-level rf radiation.¹⁶

Thermal sensations experienced by humans following exposure to E-M fields may persist after cessation of the irradiation. This effect is probably a consequence of several factors including a long latency to detection, a persistent effective temperature gradient across subcutaneous tissues and their thermal inertia, and the volume of subcutaneous tissue heated. Although changes in skin and muscle blood flow occur as a result of the increase in tissue temperature, quantitative information regarding this redistribution of thermal energy is sparse.

Indirect effects of rf fields on humans include shock and burn caused by contact with metallic objects in the field. For frequencies in the range 100 kHz to 110 MHz, the threshold for perception is 25–40 mA while that for pain is about 30–55 mA. Contact currents above 50 mA may be associated with severe burns.

The 'microwave auditory effect' can arise when the heads of humans and animals are exposed to pulse-modulated rf fields with frequencies in the range 200 MHz to 6.5 GHz, peak incident power densities of the order of 300 mW cm^{-2} , time-averaged power densities as low as 0.1 mW cm^{-2} and pulse widths varying from 1 to 100 μs . The effect is perceived as a buzzing, clicking, hissing, or popping noise depending upon modulation characteristics. The perception threshold for pulses shorter than 30 μs depends upon the energy density per pulse; the specific energy absorption threshold is around 20 mJ kg^{-1} . The most widely accepted explanation is that absorption of energy from the rf field leads to a thermoelastic interaction in the auditory cortex of the brain.^{13,17}

Investigations on the effects of occupational rf exposure on pregnancy outcome have produced both negative and positive results. Epidemiological studies of physiotherapists indicated that there were no statistically significant effects on abortion or fetal malformation¹⁸ but other studies of similar populations of female workers showed an increased risk of miscarriage and birth defects.^{19,20} Hyperthermia is teratogenic to several mammalian species including primates and has been implicated in defects of the central nervous system and facial defects in children whose mothers suffered prolonged exposure to temperatures above 39°C during the first trimester of pregnancy. Until further epidemiological data on exposed individuals and more precise quantitative assessment of the exposures involved are available, it is difficult to draw firm conclusions on reproductive risk associated with rf fields.

The few studies that address the risk of cancer following exposure to rf fields generally lack quantitative assessment of the exposures involved. Studies of populations living near rf transmitters have suggested a local increase in the incidence of leukemia but the results are inconclusive. Overall, the few pub-

lished epidemiological studies provide only limited information on rf fields and the risk of cancer.^{21–23}

The numerous studies of the effects of amplitude-modulated E-M fields, mostly involving low levels of exposure, have yielded both positive and negative results. These effects are highly dependent upon exposure parameters, the types of cell and tissue involved, and the end-points considered; they are small and difficult to relate to potential health effects.³ There is no convincing evidence of frequency and power windows in the responses to these low-level amplitude-modulated E-M fields.

The International Commission on Non-Ionizing Radiation Protection (ICNIRP), in summarizing biological effects and epidemiological studies involving frequencies from 100 kHz to 300 GHz, concluded:³ 'Epidemiological studies on exposed workers and the general public have shown no major health associated with typical exposure environments. Although there are deficiencies in the epidemiological work, such as poor exposure assessment, the studies have yielded no convincing evidence that typical exposure levels lead to adverse reproductive outcomes or an increased cancer risk in exposed individuals. ... In general, the effects of exposure of biological systems to athermal levels of amplitude-modulated electromagnetic fields are small and are very difficult to relate to potential health effects.' Other official bodies have come to similar conclusions.^{24,25}

4 MR PROCEDURES AND rf CONCERNS

The consequences of a lack of thermoregulation during exposure to rf fields from 1.5 T MR imagers are highlighted by studies carried out on anesthetized animals. In dogs, SAR values of 5.9–10.5 W kg⁻¹ led to site-specific (including deep tissues) mean temperature increases of up to 4.6°C.²⁶ In sheep, whole body SAR values of 1.5–4 W kg⁻¹ led to temperature increases in subcutaneous and deep tissues that were insufficient to produce adverse thermal effects,²⁷ although it was postulated that such effects might be produced at SAR levels around 8 W kg⁻¹. The dependence of rf dosimetry on subject size, and the thermal consequences of an impaired thermoregulatory system, must be taken into account when extrapolating these results to nonanesthetized adult humans. However, the experimental conditions may be more representative of exposure of sedated pediatric patients.

Statistically significant temperature increases of 7.5, 3.9, and 2.9°C were recorded on the upper arm, forearm, and chest, respectively, in healthy volunteers exposed to whole-body-averaged SAR values of 2.7–4 W kg⁻¹ during a 30 min procedure in a 1.5 T scanner.²⁸ The greatest increase in core temperature was 0.2°C. Fifty patients undergoing imaging of the trunk at whole-body-averaged SAR values ranging from 0.42 to 1.2 W kg⁻¹ showed a statistically significant increase in core temperature.²⁹ Increases in body temperature were greater than those in healthy volunteers, probably because these patients had impaired thermoregulation. In other investigations,^{30–32} local temperatures in patients were monitored prior to and following MRI of various anatomical sites involving averaged SAR values >0.4 W kg⁻¹. A poor correlation was found between changes in tissue temperature and whole-body-averaged SAR values.⁵ This highlights the complexity of the thermoregulatory

system and suggests the importance of assessing safety in terms of tissue temperature as well as averaged SAR. Shellock et al. studied volunteers undergoing imaging performed at whole-body-averaged SAR values of 6.0 W kg⁻¹ in cool and warm environments.³³ Although there were statistically significant increases in temperatures monitored in several body regions as well as increases in heart rate, skin blood flow, and systolic blood pressure, this level of SAR was physiologically tolerated by these individuals with normal thermoregulation. The subjective perception of heating was greater during those experiments carried out in the cool environment than in the warm environment.

Auditory perception of pulsed rf energy absorption in the human head associated with head coils was studied in six volunteers.³⁴ Frequencies in the range 2.4–170 MHz and pulse widths in the ranges 3–100 μ s were considered and the threshold pulse energy was found to be around 16 mJ. Local rf exposure with optimized surface coils positioned flush with the ear reduced the threshold to approximately 3 mJ. Radiofrequency-induced auditory noise is usually masked by noise associated with switched gradient fields.

Certain MR pulse sequences are more rf intensive than others. Fast spin echo uses rapid high-power rf pulses and leads to greater energy absorption. Magnetization transfer sequences and the less common T_1 in the rotating frame sequences also increase power to the patient, as do spectroscopic procedures involving, particularly, homo- or heteronuclear decoupling. Radiofrequency energy absorption is dependent upon the type of coil used. Small or local coils deposit less energy than large ones and circularly polarized coils require less power than linearly polarized ones. Shorter rf pulses require higher power to attain the same flip angle as achieved with longer pulses.

If the frequency dependence of the tissue dielectric properties is neglected, then the transmitted rf power required to achieve a given flip angle increases as the square of the resonance frequency ν . In reality, the power requirement will increase more rapidly since tissue conductivity increases with increasing frequency (Figure 1).

5 DOSIMETRY AND MODELING

5.1 Dosimetry and Modeling of E-M Fields

Early predictions of rf fields and power absorption associated with coils used in MR were based on geometrically simple homogenous models^{35–37} or inhomogenous phantoms.³⁸ While such studies provide valuable insight into the problem and reasonable estimates of the average rf power absorption during MR procedures, they cannot predict reliably local peak SAR levels in dielectrically heterogeneous bodies.³⁹

Beginning in the late 1980s, more realistic electromagnetic models were developed. Power absorption in the body from an idealized B_1 field (the phase was assumed to be constant across the body) associated with whole body imaging at 1.5 T was calculated using a quasistatic method.^{40,41} In quasistatic models, the inherent coupling between time-varying E and B fields is neglected and the spatial distribution of the B_1 field is taken to be that of the static field from the coil, with a superposition of the time variation, simplifying the calculation of the

field since propagation effects are ignored. Quasistatic methods are considered suitable for frequencies up to 40–60 MHz, that is when the wavelength is large compared with the dimensions of the coil and body or body region considered. At high frequencies, conduction and displacement currents lead to changes in the rf field within the subject, quasistatic approximations are inadequate, and a solution of the time-dependent Maxwell's equations is necessary. The assumption that the rf field is not perturbed by the body, inherent in the quasistatic approach, leads to an overestimation of SAR at higher frequencies.⁴²

Several techniques are available to solve time-dependent E-M field problems (method of moments, finite elements, finite differences, boundary integrals, etc.). A method apparently well-suited to the computation of rf fields in MR applications is the finite difference time domain method⁴³ in which the propagation of the rf field from its source through the dielectrically heterogeneous tissues is simulated in a time-stepped manner until the solution converges to the steady state. Such numerical methods are useful in predicting detailed structure of the rf field distribution and provide insight into the relationship between peak SAR and spatially averaged SAR values.

Tissue inhomogeneities can lead to localized peaks of induced current density and so to 'hot spots'. The patient or volunteer undergoing a MR examination is subjected to the near field of the rf transmit coil and this may also lead to localized heating close to the coil. Recent analyses of fields and SAR produced by coils for anatomically realistic cases include those in the head^{44–47} and other body parts.^{48–50}

5.2 Thermal Modeling

Thermal sequelae of rf power deposition associated with MR procedures have been studied using compartmental models that describe human thermoregulation.⁵¹ However, this approach uses SAR values averaged over the volume of the compartment and so details of local temperature fields cannot be predicted. Models that describe the detailed local heat transfer within tissues are more suited to predicting local temperature fields.

Seminal work in the development of models describing heat transfer within tissues was that of Pennes,⁵² who analyzed the quantitative relationship between arterial blood and tissue temperatures. The cooling effect of perfusion (Q_{BF}) was determined using:

$$Q_{BF} = w_b c_b K (T - T_{art}) \quad (8)$$

where w_b is the volumetric perfusion rate ($\text{kg m}^{-3} \text{ s}^{-1}$), c_b is the specific heat of blood, T_{art} is the local arterial temperature (taken to be equal to body core temperature), T is the local tissue temperature, and K is a constant ($0 \leq K \leq 1$) related to thermal equilibrium between capillary blood and local tissue. Pennes' data, when considered over a length scale of a few centimeters or more, are in very good qualitative agreement and reasonable (to within about 0.5°C) quantitative agreement with measurements. The shortcomings of this approach include the assumption that blood enters the local tissue volume at arterial temperature and leaves at local tissue temperature. In addition, heat transport related to the mass transport of blood, the actual temperature of the blood entering the local tissue volume, individual cooling or heating by large vessels, and the

effects of the complete venous vessel network are all neglected.

Considering the underlying assumptions, this approach has been successful in simulating experimentally determined elevated temperature distribution.^{50,53,54} Other studies⁵⁵ have highlighted the importance of large vessels and a high density of vessels on local heat transfer within tissues. Arkin et al. summarized several alternative thermal models and findings from experimental verifications and recommended vessel structures for which the practical implementation of the models is appropriate.⁵⁶ Thermal models that include discrete vessels and vascular trees have also been developed.^{57,58}

6 INTERNATIONAL AND NATIONAL rf SAFETY GUIDELINES

Since the main adverse effects that are likely to result from acute exposure to rf magnetic fields are those associated with responses to an increased thermal load and the effects of elevated body or local tissue temperatures, the degree of local heating must be considered in assessing safety of MR imaging and spectroscopy examinations. Burns may be caused by touching conducting objects. Several factors may contribute to an individual's decreased ability to adapt to an increased thermal load. These include old age, obesity, hypertension, and use of drugs such as diuretics, tranquilizers, sedatives, and vasodilators. Thermoregulation in infants is not well developed and heat loss from the embryo and fetus may be less than that from well-perfused tissues.

MR rf safety guidelines are based on more general safety guidelines that limit exposure to known adverse health effects.^{3,24,59,60} Some guidelines^{3,24} include basic restrictions (based directly on established health effects and reference levels derived from measurements and/or computed predictions) that provide practical exposure assessment. Federal Communications Commission (FCC) guidelines⁶⁰ on procedures for evaluating environmental effects of rf emissions incorporate limits of maximum permissible exposure (MPE) in terms of electric and magnetic field strength. Most guidelines (with the exception of the National Radiological Protection board (NRPB)^{24,61}) propose different limitations on occupational and general public exposures. Basic restrictions^{3,24} are summarized in Table 1. MPE values,⁶⁰ together with ICNIRP³ reference levels and NRPB²⁴ investigation levels, are summarized in Table 2.

For pulsed fields, conditions that invoke the microwave auditory effect in people with normal hearing should be avoided. NRPB recommends that the peak specific energy absorption in the head should be less than 10 mJ kg^{-1} over any $30 \mu\text{s}$ period.²⁴ The assessment of compliance for situations such as magnetic fields with high harmonic content, pulsed and transient magnetic fields, and exposure to the inductive near-field of rf sources is discussed by Chadwick.⁶²

NRPB MR safety guidelines^{63,64} for exposure to rf fields are intended to avoid a rise of more than 0.5°C in core temperature of patients and volunteers, including those who have an impaired thermoregulatory ability. The 'uncontrolled level' limits on time-averaged (15 min) whole-body SAR assume a specified environment (relative humidity $<50\%$ and ambient temperature $<22^\circ\text{C}$) and are 1 W kg^{-1} (for $>30 \text{ min}$), 30 W

Table 1 Basic restrictions on exposure to rf fields

Frequency	RMS current density (mA m ⁻²)		Whole-body- average SAR (W kg ⁻¹)	Localized SAR (W kg ⁻¹)			
	Head and neck	Head, neck and trunk		Head and trunk	Neck and trunk	Head and fetus	Limbs
International Commission on Non-ionizing Radiaton Protection ^a							
100 kHz to 10 MHz	$f/100^b$		0.4 ^c	10 ^d			20 ^d
10 MHz to 10 GHz			0.4 ^c	10 ^d			20 ^d
National Radiological Protection Board ²⁴							
0.1–10 MHz	$f/100$		0.4 ^e		10 ^f	10 ^g	20 ^h
10 MHz to 10 GHz			0.4 ^e		10 ^f	10 ^g	20 ^h

f , frequency (in Hz); RMS, root mean square; SAR, specific absorption rate.

For pulses of duration τ_p the equivalent frequency is determined by $1/(2\tau_p)$. For pulsed exposures in the frequency range 0.3–10 GHz and for localized exposure of the head, the specific absorption should not exceed 10 mJ kg⁻¹, averaged over 10 g tissue.

Sources: ICNIRP³ and NRPB.²⁴

^aICNIRP values are for occupational exposure; values relating to exposure of the general public are lower by a factor of 5.

^bCurrent density is averaged over a cross-section of 1 cm² perpendicular to the current direction.

^cSAR time-averaged over any 6 min.

^dSAR averaged over 10 g tissue and time-averaged over any 6 min period.

^eSAR time-averaged over any 15 min period.

^fSAR in the neck and trunk averaged over 100 g tissue and time-averaged over any 6 min period.

^gSAR in the head and fetus averaged over 10 g tissue and time-averaged over any 6 min period.

^hSAR in the limbs averaged over 100 g tissue and time-averaged over any 6 min period.

min kg⁻¹ (for 15–30 min), or 2 W kg⁻¹ (for <15 min). If core temperature, blood pressure, and heart rate are monitored, then these limits are relaxed by an additional factor of two to 'upper level' limits. For exposure of body parts, the local SAR limit should prevent local temperature exceeding 38°C in the head and fetus, 39°C in the trunk, and 40°C in the limbs. The local SAR (averaged over any 1 kg tissue and period of 6 min)

limits (for >30 min) are 2, 4, and 6 W kg⁻¹ for the head and fetus, trunk, and limbs, respectively. For shorter periods, the corresponding limits are 60, 120, and 180 W min kg⁻¹ (for 15–30 min) or 2, 4, and 6 W kg⁻¹ (for <15 min). The Medical Devices Directorate (MDD) guidelines, based on the NRPB's two-level approach to limits, include a normal mode of operation (when exposure is less than the uncontrolled level), a

Table 2 Reference levels, investigation levels, and maximal permissible exposures (MPE) to rf fields

Frequency	Magnetic field strength (A m ⁻¹)	Magnetic flux density (μT)	Electric field strength (V m ⁻¹)	Equivalent plane-wave power density (W m ⁻²)
International Commission on Non-ionizing Radiation Protection reference levels ^a				
1–10 MHz	$1.6/f^{b,c}$	$2.0/f^{b,c}$	$610/f^{b,c}$	–
10–400 MHz	0.16^b	0.2^b	61^b	10^b
National Radiological Protection Board investigation levels ^d				
12–200 MHz	0.13	0.16	50	6.6
200–400 MHz	$0.66f^e$	$0.70f^e$	$250f^e$	$(165f^2)^e$
Levels when there is no possibility of small children being exposed				
10–60 MHz			60	10
60–137 MHz			$1000f^e$	$(2700f^2)^e$
0.137–1.1 GHz			137	50
Federal Communications Commission MPE ^f				
3.0–30	$4.89/f^{b,c}$		$1842/f^{b,c}$	$(9000/f^2)^{b,c}$
30–300	0.163^b		61.4^b	10^b
300–1500	–		–	$f/30^{b,c}$

^aReference levels for occupational exposure to rf fields.³

^bTime-averaged over any 6 min period.

^c f , frequency in MHz.

Table 3 The International Electrotechnical Committee limits on specific absorption rates (SAR)¹⁰

	Normal operating mode	First level controlled operating mode	Second level controlled operating mode
Whole-body SAR ^a	$\leq 1.5 \text{ W kg}^{-1}$ averaged over 15 min	$\leq 4 \text{ W kg}^{-1}$ averaged over 15 min	$>4 \text{ W kg}^{-1}$ averaged over 15 min
Head SAR ^a	$\leq 3 \text{ W kg}^{-1}$ averaged over 10 min	Not applicable	$>3 \text{ W kg}^{-1}$ averaged over 10 min
Local tissue SAR ^b		Not applicable	
Head and torso	$\leq 8 \text{ W kg}^{-1}$ averaged over 5 min		$>8 \text{ W kg}^{-1}$ averaged over 5 min
Extremities	$\leq 12 \text{ W kg}^{-1}$ averaged over 5 min		$>12 \text{ W kg}^{-1}$ averaged over 5 min

It is assumed that the SAR averaged over any 10 s period does not exceed five times the stated time-averaged SAR limit.

^aValues of SAR averaged over the whole body or over the head.

^bLocal tissue SAR is the value of SAR averaged over any 1 g tissue.

controlled mode (when exposure is between the uncontrolled and upper levels), and a mode that is not recommended (for exposures above the upper level).⁶⁵

The International Electrotechnical Committee (IEC) also defines SAR limits for three differing modes of operation (Table 3).¹⁰ All persons, regardless of health status, should be able to tolerate the normal operating mode. The first-level controlled operating mode should be tolerated by people with unimpaired thermoregulatory and cardiovascular systems; however, since individual tolerance to hyperthermia is variable, medical supervision is required. Second-level controlled operating mode exposures require a protocol that is approved by a local ethics committee or investigational review board. Like earlier recommendations,⁶⁴ these guidelines also assume moderate environmental conditions (temperature $<24^{\circ}\text{C}$ and relative humidity $<60\%$). Under the first-level controlled operating mode, whole-body SAR limits should be decreased by 0.25 W kg^{-1} for each 1°C above 24°C , and by 0.1 W kg^{-1} for each 10% increase in relative humidity. For the normal operating mode, the reductions in SAR limits should be reduced by a factor of two.

The Food and Drug Administration considers that MR investigations in which SAR is greater than 4 W kg^{-1} whole body for 15 min, 3 W kg^{-1} averaged over the head for 10 min, 8 W kg^{-1} in any 1 g tissue in the head or torso for 15 min, 12 W kg^{-1} in any 1 g tissue in the extremities for 15 min are 'significant risk'.⁶⁶ This is a relaxation of earlier guidance that had stated a level of concern related to whole body rf heating of 0.4 W kg^{-1} or that resulting in an increase in core temperature of 1°C . The new level is in accord with the first-level controlled mode in IEC¹⁰ and operation resulting in SAR values above this level requires an approved human studies protocol.

7 FUTURE DEVELOPMENTS IN rf SAFETY

Widely used multi-echo sequences are time efficient but can greatly increase rf exposure compared with conventional methods. Even in routine examinations, it is not uncommon for operators to have to modify sequence parameters in order to remain within the limits imposed by manufacturers to ensure that scanners operate within safety regulations. These practical limits are generally based on relatively simple, spatially averaged models. By being conservative, safety is assured but the restrictions imposed increasingly impact on routine practice. There has also been a proliferation in the routine use of

specialist coils with a trend towards close-coupled designs and use of local transmit systems, particularly for spectroscopy. Such trends create a pressing need for assessment of localized SAR and temperature changes in a realistic manner.

1 INTRODUCTION

Advances in medical imaging over the last several decades have provided important new diagnostic capabilities. Yet, it is generally agreed that there is still considerable scope for further development. Medical imaging technologies such as computed tomography (CT), ultrasonography, and MRI can be regarded as methods for obtaining maps depicting various tissue properties such as X-ray attenuation, echogenicity, and magnetic properties, respectively. What other tissue properties might be useful to probe by imaging?

The time-tested value of palpation as a diagnostic tool used by physicians provides motivation for seeking methods to image the mechanical properties of tissue. In some series, for example, 30% of breast cancers are detected only by palpation and not by mammography.¹ It is also not uncommon during abdominal operations for surgeons to discover tumors by palpation that were previously undetected by CT, MRI, or ultrasound.

The value of palpation stems from the fact that many disease processes such as neoplasia can dramatically alter the mechanical properties of tissue.² There is some evidence that changes in tissue elastic properties may accompany early stages of carcinogenesis, and that such changes might even have some degree of predictive value for certain types of cancer.³⁻⁵ Tissue mechanical properties are not directly assessed by any of the available conventional imaging techniques, such as CT, ultrasound, or MRI: they are distributed over a much larger range than the physical properties assessed by conventional imaging modalities (Figure 1).

These considerations provide a rationale for seeking practical methods for 'palpation by imaging'. The potential value of such technology might be used to assess regions of the body that are not accessible to the physician's hand, to reveal lesions that are too small to detect by touch, and to provide new parameters for tissue characterization.

2 THEORY OF MEASURING TISSUE ELASTICITY

A straightforward approach for measuring the mechanical properties of an object is to apply a known stress to the object and then to measure the resulting strain response in some way. The response of an object following some external stress is either rigid body motion or deformation. Deformation, unlike rigid body motion, depends entirely on the material properties of that object, which can be reversible (elastic), irreversible (viscous, plastic, or flow) or a combination of the two. Soft tissues, for the most part, are a combination, known as viscoelastic.

Given that the measure of applied load (stress tensor) and the measure of deformation (strain tensor) are linearly related for an infinitesimally small elastic deformation, this simple equation follows.⁶

$$\sigma_{ij} = C_{ijkl}\gamma_{kl} \quad (1)$$

where σ_{ij} is the stress tensor, γ_{kl} is the strain tensor, and C_{ijkl} is the elastic modulus tensor. A full description of the elastic modulus tensor of a material requires as many as 81 independent constants. Soft tissues, however, given a few simplifying assumptions, can be described by as few as two constants.

There are four most commonly used elastic constants for characterizing materials: bulk elastic modulus (K), shear elastic modulus (μ), Young's modulus (E), and Poisson's ratio (σ). For an isotropic, Hookean solid, the shear and bulk elastic moduli are related to Young's modulus and Poisson's ratio by the following relationships:⁶

$$\mu = \frac{E}{2(1 + \sigma)} \quad (2)$$

$$K = \frac{E}{3(1 - 2\sigma)} \quad (3)$$

Soft tissues, however, are generally neither isotropic nor Hookean. Additionally, the elastic moduli can depend on the scale of deformation and temporal behavior of applied stress. Nevertheless, these parameters are adequate for approximating the mechanical properties of soft tissues.^{2,3,7}

Poisson's ratio, which describes the ratio of lateral contraction to longitudinal elongation, ranges from 0.490 to 0.499 for most soft tissues. This very small dynamic range limits its value as a contrast parameter for soft tissue elasticity imaging. According to Equation (2) and with this ratio being very nearly 0.5 (the reason soft tissues are described as incompressible),

Figure 1 Spectrum of physical parameters that may be used to evaluate biological tissues. The shear modulus of soft tissues ranges over five orders of magnitude. Available soft tissue contrast is much less for conventional ultrasonography, X-ray-based imaging modalities, and MRI. CSF, cerebrospinal fluid

Young's modulus is simply related to shear modulus by a factor of three: $E=3\mu$.

The bulk modulus describes the response of a material to a change in its volume. The relationship between longitudinal mechanical wave speed (ν_l) and the bulk elastic modulus is:

$$K \approx \nu_l^2 \rho \quad (4)$$

where ρ is the density of the medium. The bulk modulus variations in soft tissues are less than a few per cent, and bulk modulus variations with respect to mechanical wave frequency are also within a few per cent. Bulk modulus then, like Poisson's ratio, offers little contrast as an elasticity parameter.

By comparison, shear elastic modulus describes the changes of a material in response to changes in its shape. The relationship between shear wave speed (ν_t) and shear elastic modulus is given by:⁸

$$\mu \approx \nu_t^2 \rho \quad (5)$$

Equations (4) and (5) are similar, but unlike the bulk elastic modulus the shear elastic modulus varies greatly within soft tissues. In addition, the value of the latter is highly dispersive over a broad range of frequencies, unlike the bulk modulus, which is basically nondispersive in soft tissues.^{9,10}

Investigators have attempted to use a variety of forms of mechanical stress for the purpose of assessing mechanical properties, including both endogenous and exogenous sources. Endogenous sources of stress, such as respiration and cardiac pulsations, essentially allow for only a qualitative estimate of tissue elasticity because the stress distribution is unknown.

Exogenous stress sources can be static or quasi-static as well as time-varying periodic mechanical waves. In a quantitative sense, the main disadvantage of static and quasi-static compressions is that it is difficult to know the boundary conditions with sufficient accuracy to characterize the input stress distribution appropriately.

Time-varying periodic sources of stress, such as mechanical waves, can be longitudinal or transverse. Longitudinal waves are not ideal sources of stress because their behavior is governed by the bulk modulus which varies by only a few per cent within soft tissues. Transverse mechanical waves could be used as a source of stress, but frequencies greater than 500 Hz attenuate greatly in soft tissues, thereby limiting their use. Therefore, very-low-frequency transverse acoustic mechanical waves remain as a source of stress for quantitative elasticity imaging.

Existing techniques to measure the strain response within tissues noninvasively are based on conventional echo ultrasound and various MRI methods.^{2,3,7,11–36} Ultrasound-based methods are, to some extent, limited by the fact that they are only capable of measuring the component of motion that occurs along the axis of the beam. They are also limited by the necessity of finding an acoustic window into the body. MRI, in principle, is capable of measuring 3D displacements of soft tissues within the body with moderate spatial resolution.

More recently, an MRI-based technique has been described that is capable of providing quantitative images depicting tissue elasticity.^{37,38} This technique, called magnetic resonance elastography (MRE), uses low-frequency transverse mechanical

waves as the source of stress (for reasons described above) and uses MR-based methods to measure the small displacements caused by the low-frequency oscillating stress. MRE is capable of quantifying shear elastic modulus in biological tissues, both ex vivo and in vivo.^{10,36–41} The technique is reviewed in the following sections.

3 THEORY OF MAGNETIC RESONANCE ELASTOGRAPHY

It is well known that MR experiments can be designed with exquisite sensitivity to measure spin motion, from bulk motion to microscopic diffusion.^{42–49} Conventional MRI encodes the spatial position of spins with appropriate magnetic field gradients.^{50,51} If the position of the spin varies in the presence of a gradient, it can induce a phase shift in the received signal.⁴⁵ This is the basis of phase contrast-based MRI sequences, which provide a versatile means of measuring spin motion.^{44,45,48} With special modifications, such sequences can be designed to measure the cyclic motion of fluid in the cochlea resulting from applied sound,⁵² and cyclic motion of tissue caused by applied propagating shear waves.^{37,38}

Based on the discussions in the previous section, MRE uses externally applied low-frequency transverse mechanical waves to probe the object. This requires that small cyclic displacements caused by the propagating mechanical waves be detected using appropriate motion-encoding gradients. In MRE, the motion-sensitizing gradients are cyclic and the frequency of the gradient waveform is the same as that of the mechanical excitation. Such cyclic motion-sensitizing gradient waveforms can act as 'filters' to detect only the shift caused by spin motion occurring at the desired frequency. Very small cyclic motion (of the order of nanometers) can be detected using cyclic magnetic field gradients that are phase-locked with the spin motion. (A detailed description of the formalism behind the principles of acoustic wave imaging is presented by Muthupillai et al.³⁷)

The phase shift (φ) induced in the received NMR signal by cyclic motion caused by a mechanical wave propagating within a medium at a given frequency ($1/T$), in the presence of a cyclic motion-encoding gradient, is given by the following expression:

$$\varphi(\vec{r}, \alpha) = \frac{\gamma NT(\vec{G} \cdot \vec{\xi})}{2} \cos(\vec{k} \cdot \vec{r} + \alpha) \quad (6)$$

The above equation indicates that the accumulated phase shift is proportional to the scalar product of the gradient vector $\vec{G}$ and the displacement vector $\vec{\xi}$, the number of gradient cycles (N), and the period of the gradient waveform (T). The quantity γ is the gyromagnetic ratio, α is the phase relationship between the motion-encoding gradient and the externally applied mechanical excitation, and $\vec{r}$ is the nuclear spin position vector. The scalar product relationship indicates that wave motion occurring along any direction can be measured. Equation (6) indicates that the sensitivity of the method to spin motion can be enhanced by increasing the number of gradient cycles (within the limitations of the spin-spin relaxation time) or by increasing the amplitude of the encoding gradient (within the hard-

ware limitations of the imager) or by both. The measured quantities, the spin displacement ξ and the wave vector $\vec{k}$, can yield information about the mechanical properties of the material (which will be discussed in detail in the next section).

Similar to other phase contrast-based techniques, two measurements are acquired by alternating the polarity of the motion-encoding gradients between the measurements. This process not only increases the sensitivity of the technique but also reduces any systematic errors. The phase images (generated from each acquisition) are then subtracted to yield a phase difference image that reflects the phase shift caused by the propagating mechanical wave.

The experimental method to obtain such ‘wave’ images is shown in Figure 2. Note that the motion-sensitizing gradients act synchronously with the applied mechanical motion. By varying the time, θ , between the onset of the mechanical motion and the beginning of the motion-sensitizing gradients, the propagating waves can be ‘captured’ at various points throughout their cycle. This makes it possible to study the temporal behavior of propagating waves.

By superimposing gradients along any desired direction, the component of spin motion in that direction can be measured. Thus, by acquiring volumetric data with motion encoding along all three directions, the 3D wave vector can easily be computed for a volumetric object. The ability to measure the 3D wave vector makes it possible for MRE to estimate elasticity measurements robustly.

4 ESTIMATING SHEAR ELASTIC MODULUS

From the acquired displacement maps, wavelength and displacement amplitude of the propagating waves are the two parameters that can be directly measured. The mechanical properties of wave speed, strain, attenuation, and shear elastic modulus can then be derived from this information. In a simple homogeneous material, ν_t is easily calculated from the wavelength (λ) of the shear wave and the frequency of the externally applied mechanical excitation (f):

$$\nu_t = f\lambda \quad (7)$$

The simple definition of the shear modulus given in Equation (5) is only true for purely elastic materials. In viscoelastic tissues, true wave speed depends on the viscous properties of the material as well. This relationship is given by:⁵³

$$\nu_t = \sqrt{\frac{2(\mu_1^2 + f^2\mu_2^2)}{\rho(\mu_1 + \sqrt{\mu_1^2 + f^2\mu_2^2})}} \quad (8)$$

where μ_1 is the coefficient of shear elasticity, μ_2 is the coefficient of shear viscosity, ρ is density, and f is the frequency of the mechanical wave. When $\mu_2=0$, as in a purely elastic material, or $f\mu_2 \ll \mu_1$, Equation (8) can be reduced to Equation (5). The frequency-dependent viscous properties of soft tissues

Figure 2 Schematic diagram of a magnetic resonance elastography experiment. The conventional gradient echo pulse sequence for spatial encoding is shown at the bottom left. Superimposed onto each axis are the cyclic motion-sensitizing gradients (shaded areas). As shown at the top left, these gradients oscillate with the motion driver that applies acoustic shear waves to the object. The phase offset (θ) between the onset of the gradients and the triggering of the driver can be varied to allow multiple time offsets for the propagating waves to be captured at various points throughout their cycle

Figure 3 A frequency dispersion curve of a tissue-simulating phantom (18% bovine gel) illustrating the viscous properties of soft tissues. Apparent shear modulus increases with increasing acoustic wave frequency

may be an important contrast parameter that could be further explored for better tissue characterization. In fact, our experiments have shown that tissues and tissue-simulating materials show frequency dispersion; that is, the shear modulus increases with increasing frequency (Figure 3).¹⁰ However, the simplified estimation of shear modulus in Equation (5) is a reasonable approximation for most soft tissues.

The wavelength from the acquired wave images in a homogeneous material is sufficiently estimated by fitting the acquired displacement amplitude profile to a damped sinusoidal function. For heterogeneous material, however, it is necessary to estimate the wavelength of the propagating waves in local regions of the image so that an estimate of the local shear modulus throughout the material can be made.

Several techniques have been presented to estimate the local wavelength, and others are currently being investigated. For heterogeneous materials, a local frequency estimator (LFE) algorithm can be applied to the wave images to estimate the wavelength at each point in the image.^{54–58} This algorithm estimates the local spatial frequencies (or wavelengths) by constructing lognormal quadrature wavelets (acting as filters) and combining the local estimates of instantaneous spatial frequency obtained from these filters. We have shown that this algorithm is isotropic and can estimate the wavelength accurately, even on either side of a transition between two regions of different stiffnesses.^{54,55} We have made some modifications to the basic algorithm so that it functions well in the presence of noise.

Additionally, by obtaining a series of ‘snapshots’ of the acoustic wave propagating within the material, it is possible to perform a Fourier transformation along the time axis to extract the desired component of motion. The LFE can be applied to these time-filtered wave images to help to reduce the noise and other systematic errors that may be present in the data. It has been shown that the resolution at which this technique can correctly calculate local wavelength and, therefore, quantify shear modulus, is about one quarter to one half of a wavelength.⁵⁴ Simulations have shown, however, that smaller than one eighth

of a wavelength may be adequate for a simple qualitative assessment of tissue elasticity. That is, a very small stiffer inclusion can be resolved from the softer surrounding material, but the actual wavelength the algorithm calculates within that small inclusion may not be accurate.⁵⁹

5 EXPERIMENTAL RESULTS AND PROOF OF CONCEPT

In all the experiments shown, the source of propagating shear waves is an electromechanical driver triggered synchronously with the motion-encoding gradients. An alternating current is pulsed through the driver, which is simply a small resistive coil, creating an associated alternating magnetic field. When the coil axis is not aligned with the main magnetic field, the resulting torque between the two fields can be used to create cyclic motions. This kind of driver is capable of delivering frequencies of vibration in the desired acoustic range of 10–1000 Hz.

Tissue-simulating phantoms were first used as a medium to show that propagating acoustic shear waves can be visualized using MRE and that shear modulus measurements can be estimated. Imaging was done in a conventional 1.5 T imager. Figure 2 graphically illustrates a typical experiment with a gel phantom, the electromechanical driver, and the motion-encoding pulse sequence. The resulting displacements caused by the planar wavefront in the gel are visualized.

The pulse sequence for these experiments is a standard gradient echo sequence. For all experiments shown here, the added motion-encoding gradients $\vec{G}(t)$ were applied collinear with the applied direction of motion $\vec{r}(t)$ and perpendicular to the direction of wave propagation. Typical imaging parameters are TR 50–300 ms, TE 15–60 ms, number of views 128–256, acquisition time 20–120 ms, flip angle 10–60°. Mechanical excitations ranged from 100 to 1100 Hz, and the number of gradient pulses ranged from 2 to 30 cycles. After acquiring two acquisitions, each with the motion-sensitizing gradients opposite in polarity, the phase images are subtracted. This phase-difference image is referred to as a ‘shear wave’ image. A group of 6 to 16 wave images were acquired, each with a slightly different time offset between the onset of the mechanical stimulation and the onset of the motion-sensitizing gradients. This offset enables multiple ‘snapshots’ of the waves at various points throughout their cycles to be acquired (see Figures 6 and 7, below).

Once the multiple time offset wave images have been acquired, the data are processed to calculate shear modulus. Figures 4 and 5 show wave images in gel phantoms at 250 Hz and the resulting quantitative shear modulus maps calculated using the local wavelength estimator. Figure 4a is a wave image of a gel phantom with two cylindrical inclusions of different stiffnesses. One inclusion is softer than the surrounding gel, and the other is stiffer. The changes in wavelength (increased wave speed in the stiffer gel and the decreased wave speed in the softer gel) are apparent within each inclusion in the wave image. The computed elastogram is shown in Figure 4b and quantifies the calculated shear modulus.

Figure 5 shows a gel phantom comprising an oblique slab of soft gel bounded by stiffer gel on the top and bottom. Figure 5a shows a single wave image of the propagating shear waves.

Figure 4 Magnetic resonance elastography of an agarose gel phantom with two inclusions, the outlines of which are shown by dotted circles. The inclusion on the left is stiffer than the surrounding gel and the inclusion on the right is softer. Shear motion at 250 Hz was applied to the top surface of the gel and is along the right–left direction. (a) The shear wave image in which the resulting displacements are shown in color and quantified at the bottom of the figure. The changes in wavelength within the inclusions are apparent, as well as a refraction phenomenon in the softer inclusion causing a focusing effect. (b) Quantitative map of shear modulus produced by calculating the local wavelength at each pixel from the shear wave images. It shows that the stiffer inclusion is about 22 kN/m² and the softer one is about 6 kN/m². Reprinted with permission from Muthupillai et al.³⁷ Copyright 1995 American Association for the Advancement of Science

The change in the direction of the wavefront as it reaches the interface between the stiff and the soft gel compartments is evident. The decrease in wavelength as the waves travel from the upper stiffer gel to the middle softer gel can also be clearly

seen again. The wavelengths lengthen again as they traverse the stiff layer at the very bottom. The elastogram shown in Figure 5b correctly depicts the stiffer upper, softer middle, and stiffer lower layers.

Figure 5 Magnetic resonance elastography of a phantom comprised of three oblique slabs of agarose gel. The upper and lower layers are stiffer than the softer middle layer. Shear motion at 250 Hz was applied to the top surface of the phantom. The measured displacements are between +5 and −5 μm. (a) Shear wave image showing the deflection of the waves and change in wavelength as they traverse the different interfaces. Images of multiple phases are processed to calculate the local wavelength at each pixel with the local frequency estimator algorithm. (b) Quantitative elastogram generated by processing the wave images is color coded to show the shear modulus values. Reproduced with permission from *Nature Medicine* 2, 601–603, 1996

Figure 6 Propagating acoustic waves at 100 Hz in the human brain, observed with magnetic resonance elastography (MRE) in vivo. Low-amplitude intracranial acoustic waves were generated via inertial interactions using an electromechanical driver coupled to the head of normal volunteers. MRE wave images were used to warp a transverse T_1 -weighted anatomic image using a 3D rendering program to create this visualization. The apparent amplitudes of the waves are magnified approximately 10000 times from the actual amplitude of brain motion. The pattern of shear wave displacement reflects the applied ‘nodding’ motion, with shear waves arising 180° out of phase at the anterior and posterior dural surfaces. Prominent shear waves are also generated in the posterior region of the falx

6 IN VIVO AND EX VIVO EXPERIMENTS

We have demonstrated that MRE is feasible in tissue-simulating materials. We have also shown that shear waves can be generated and imaged in biological tissues, both in vivo and ex vivo. Ex vivo biological tissues that are currently under investigation using MRE include human prostate specimens and porcine liver, kidney, and muscle specimens. Shear waves have also been successfully generated and imaged in vivo in

brain, skeletal muscle, and breast of human volunteers (Figures 6–8).

Shear waves in the brain are shown in Figure 6. The source of wave motion was a bite-bar moving at 100 Hz that was grasped by the teeth of a volunteer. The resulting inertial effects caused the shear waves to propagate through the brain with very small displacement amplitudes. The 3D rendition in Figure 6 magnifies the actual displacements by about 10000 times.

Figure 7 Propagating acoustic waves in human skeletal muscle in vivo shown by magnetic resonance elastography (MRE). An electromechanical driver was used to apply 150 Hz shear waves with about $100\ \mu\text{m}$ amplitude to the distal musculotendinous junction of the biceps brachii muscle. (a) A sketch of an axial section of the arm showing the location of the coronal plane that was imaged using MRE. (b) Imaging of this coronal slice with the MRE sequence depicts propagating acoustic waves. The field of view in this figure is 20 cm and the flexion loading on the arm was 12 lb (26.4 kg). By varying the time offset between the applied mechanical waves and the cyclic motion-encoding gradients (θ in Figure 2), the temporal pattern of wave propagation can be observed. (c) A vertical strip from the wave image (indicated by the highlighted section in (b)) is shown at various phase offsets in the wave cycle. The steepness of the diagonal pattern (wave velocity) was observed to depend on muscle loading

Figure 8 An example of in vivo propagating acoustic waves in the breast of a volunteer. (a) An axial T_1 -weighted spin-echo image of the breast showing the section of tissue evaluated in (b). (b) A color representation of the propagating acoustic shear waves. This is a single snapshot of the propagating waves in time at a mechanical frequency of 100 Hz. The mechanical motion is through-plane, so tissue displacement into the plane is represented as shades of blue, and displacement out of the plane is represented as shades of red. The waves are propagating toward the chest wall

Shear waves were visualized in the human biceps brachii by tapping the distal musculotendinous junction of the muscle at a frequency of 150 Hz. The amplitude of the applied motion was about $100\ \mu\text{m}$. During the experiment the muscle was slightly flexed and under a small amount of load. The wave image shown in Figure 7b is from a coronal slice of the muscle. The motion-encoding direction was along the slice-select direction, and the component of the displacement caused by the propagating wave in the slice-select direction is shown. The imaging plane was chosen so that the orientation of the muscle fibers was in the imaging section. Eight different snapshots of the wave propagating within one section of the muscle are shown in Figure 7c.

An example of the ability to visualize wave propagation in human breast tissue in vivo is shown in Figure 8. The volunteer is in the prone position with an electromechanical driver coupled to the anterior part of the breast. Mechanical motion is in the superior–inferior direction and the resulting shear waves propagate toward the chest wall. Adequate penetration is usually achieved with mechanical frequencies in the range 75–200 Hz.

The wave propagation in a 3D heterogeneous object such as soft tissues in vivo is very complex. We are continuing to refine both our acquisition techniques as well as the post-processing methods, to allow a robust characterization of the elasticity of soft tissues in vivo. We are also continuing to

evaluate the elasticity of various normal and cancerous tissues in vivo and ex vivo.

7 SUMMARY

MRE is a new imaging technique that shows promise for noninvasive evaluation of the mechanical properties of tissues and tissue-like materials. By choosing an appropriate motion-sensitizing gradient waveform, it is possible to visualize and measure externally applied propagating mechanical waves within phantoms and tissues. From these measurements, it is possible to estimate the mechanical properties of the material under investigation quantitatively.

Preliminary experiments have shown that it is possible to visualize shear waves propagating within materials in vivo, specifically in the brain, skeletal muscle, and breast of volunteers. Future work will involve more extensive tissue characterization experiments using MRE for evaluating the mechanical properties of normal and pathological tissues. These tissue characterization experiments will provide the necessary information to further optimize experimental methods to visualize shear waves in vivo. Further efforts are attempting to refine both acquisition methodology (to include rapid 3D acquisitions with motion encoding along all three cardinal axes) and image-processing techniques to analyze the complex wave propagation observed in vivo.

The development of an elasticity imaging modality that can accurately assess the mechanical properties of soft tissues could aid in the detection and characterization of pathological tissues. The large scale of contrast available by imaging the mechanical properties of tissues may lead to an elasticity imaging modality that is more sensitive in the early detection and characterization of certain diseases compared with standard imaging modalities.

Staff scientist at Philips Medical Systems 1998–present. Research interests: elasticity imaging, measuring physiological function with MRI.

Richard L. Ehman. *b.* 1952. B.Sc. (Physics), 1974, M.D., 1983. Diagnostic Radiologist, involved in clinical and technical development of MRI since 1983. Recipient of ISMRM Gold Medal in 1995. Approx. 150 scientific publications and 12 patents. Research interests: elucidation of motion artifacts in MRI and development of correction methods, vascular MRI, fast imaging, and development of MRI methods for assessing viscoelastic properties of materials.

Hyperpolarized Gas Imaging

James R. MacFall

Duke University Medical Center, Durham, NC, USA

and

Bastiaan Driehuys

Magnetic Imaging Technologies, Inc., Durham, NC, USA

1 INTRODUCTION

Hyperpolarized gas imaging has been enabled by fundamental research in atomic physics^{1–3} and in techniques for producing spin polarized targets to study elementary particle physics.^{4–8} The polarization of a spin-1/2 substance is defined as the difference in the percentage of nuclear spins that are in the $m_z = +1/2$ state versus the $m_z = -1/2$ state.⁹ Even with the most powerful magnets, it is difficult to attain a polarization that is greater than a few parts per million. This is the reason that nuclear magnetic resonance (NMR) is often referred to as being a low-sensitivity technique. For the protons on a water molecule, the small polarization is compensated for, somewhat, by the high concentration of nuclei. Consequently, MRI of protons in the water and lipids in living subjects can be performed with adequate signal-to-noise ratios (SNR) in modern MRI systems.

Recent extension of the research on spin polarization has made it possible to polarize in liter quantities the spins of certain noble gases, such as ^3He and ^{129}Xe , to levels near 100%. While gases do have much lower density than water at room temperature, the huge increase in polarization, of the order of a factor of 10^5 , more than compensates for this loss.

In human and animal subjects, water proton MRI provides adequate images for most of the body. There are regions of the body that are not available to conventional MRI because of low proton spin concentration, such as the lung air spaces, the cranial sinus cavities, the bowel, and the nasopharynx. Since both ^3He and ^{129}Xe are gases that are biocompatible, these regions are obvious candidates for application of hyperpolarized gas MRI. The first application of this technique in vivo was accomplished in guinea pig lungs in 1994 using ^3He .¹⁰

Other possible applications of this new source of MRI signal have been suggested. It appears possible to suspend bubbles of these gases in liquids that can be injected into a living subject for improved blood flow or perfusion images.¹¹ Also, since ^{129}Xe is transported to the blood from the lungs, this may provide a noninjected blood perfusion measure for the brain, heart, or other organs.^{12,13} Finally, there may be applications in nonliving systems for nondestructive testing, such as evaluation of tiny cracks in materials or studying the movement of gas through porous media.

The first section of this chapter describes the properties of ^3He and ^{129}Xe , the two gases that have been used successfully in hyperpolarized gas imaging, and the polarization methods

that have been developed for their use. The following section describes the most common imaging methods that have been used in animals and humans, and some of the results obtained.

2 THE GAS POLARIZATION PROCESS

2.1 Magnetization and Polarization Concepts

The signal strength in a given image voxel is proportional to the amount of magnetization present in that voxel. The magnetization M of a substance is given by $M = \mu n P$, where μ is the nuclear magnetic moment, n is the density of nuclei, and P is the degree of polarization of these nuclei. Polarization is defined as the difference in the fraction of nuclear moments which are aligned ($N_\uparrow$) with the magnetic field versus anti-aligned ($N_\downarrow$):

$$P = \frac{N_\uparrow - N_\downarrow}{N_\uparrow + N_\downarrow} \quad (1)$$

In conventional proton MRI, this polarization is determined by thermodynamic equilibrium and amounts to only about 5 ppm in a 1.5 T magnetic field. However, because the proton density n is so high in most substances ($n = 7 \times 10^{22}$ protons cm^{-3} in H_2O) very strong signals can be achieved. By contrast, a gas at standard temperature and pressure has a density of only about 2.6×10^{19} nuclei cm^{-3} , which corresponds to a decrease in signal relative to liquids of about 2700. For these reasons, gases have not been seriously considered as good imaging agents for MRI. Recently matured technologies now enable an artificial increase of the nuclear spin polarization of certain noble gases by as much as five orders of magnitude above thermal equilibrium. This polarization increase more than overcomes the spin density sacrifice of gases relative to liquids.

2.2 Methods of Gas Polarization

There are effectively only two gases, ^3He and ^{129}Xe that exhibit sufficiently long relaxation time to be amenable to hyperpolarization. Diatomic molecular gases are poor candidates because the coupling of the nuclear spin to rotational angular momentum of the molecule results in rapid relaxation. This leaves only noble gases as potential candidates for hyperpolarization. The only noble gas isotopes that are both stable and have a spin of 1/2 are ^3He and ^{129}Xe . Isotopes with higher spin values possess a quadrupole moment that couples to electric field gradients to cause rapid relaxation. While noble gases with higher nuclear spin have been polarized to some extent, the polarization levels are generally low, and the lifetime of the polarization is short.¹⁴

There are several methods for inducing hyperpolarization. Perhaps the most intuitive are the thermodynamic equilibrium polarization methods. In principle, by cooling the gas to low temperatures and using extremely high magnetic fields, nuclear spin polarizations of nearly 100% could be attained. Such methods are just now being explored and are technically quite challenging. Calculations indicate that with a magnetic field strength of 15 T and a temperature of 5 mK, ^3He polarizations of 96% could be achieved.¹⁵ However, no practical implementations of such schemes have been realized to date.

The two more mature techniques for inducing hyperpolarization in noble gases involve the indirect transfer of angular momentum from photons to atomic electrons and then to nuclear spins. One technique called metastable optical pumping was originally developed by Colegrove, Schearer, and Walters¹⁶ and is suitable only for polarizing ^3He . The other hyperpolarization method, which is capable of polarizing either ^3He or ^{129}Xe , is called optical pumping and spin exchange (OPSE).

2.2.1 Polarization of ^3He

The present state-of-the-art method, the metastability exchange ^3He hyperpolarization system, was developed by a group at Johannes Gutenberg-Universität Mainz.¹⁷ In this technique, low pressure ($\sim 1\text{--}3$ mbar) ^3He gas is held in an rf discharge, promoting a small fraction of the atoms to an excited metastable $1s2s^3S_1$ state. From this state, the ^3He gas is able to absorb circularly polarized light at a wavelength of 1083 nm. Absorption of this net angular momentum from the photons induces a high degree of electron spin polarization in the gas that is then transferred through the hyperfine interaction to the ^3He nuclei. The Mainz system incorporates four 1 m long optical cells to absorb roughly 4–11 W of laser power from an $\text{La}_{0.83}\text{Nd}_{0.15}\text{MgAl}_{11}\text{O}_{12}$ laser. The gas in the optical cells is polarized with a time constant of about 25 s. However, because the gas is at very low pressures, it must then be compressed to atmospheric pressure to become useful for imaging. This compression is achieved through a specialized titanium piston that does not induce significant depolarization. The present stated performance of this polarizer is a polarization level of 50% achieved at a production rate of 0.5 l h^{-1} and further

improvements are being forecast. The only drawbacks of this elegant approach are that the system can be quite large and costly and is limited to polarizing ^3He .

The other hyperpolarization method, which is capable of polarizing either ^3He or ^{129}Xe , is OPSE (Figure 1). In this technique, an alkali metal such as Rb is used to absorb circularly polarized laser light (795 nm for Rb). This absorption of net angular momentum from the laser beam preferentially depopulates only one of the valence electron spin states of the alkali metal. Eventually all of the electrons are ‘optically pumped’ into the other spin state, causing a large electron spin polarization. This electronic polarization is then transferred via collisions to the noble gas nucleus of interest. During a Rb– ^3He collision, the valence electron of the Rb atom overlaps briefly with the nucleus of the ^3He atom. This hyperfine contact interaction can cause a simultaneous spin flip of the ^3He nuclear spin and the Rb valence electron spin or ‘spin exchange’. After such a collision, the Rb atom becomes repolarized through absorption of another photon and the process continues. The polarization of the noble gas builds up exponentially, akin to the charging of a capacitor. Time constants for this process can range from many hours to just a few seconds depending on laser power, gas composition, and other factors.

Polarization of ^3He through spin exchange with optically pumped Rb has been studied since 1960.¹⁸ However, it is only recently that advances in high-power laser technology have made production of liter quantities of polarized ^3He practical. Several university research groups have built systems for gas polarization using this approach. A commercially manufactured unit even exists (Magnetic Imaging Technologies (MITI), Durham, NC, USA), as pictured in Figure 2, illustrating the compactness of such a system, which can fit in a hospital hall-

Figure 1 The optical pumping and spin exchange method of producing hyperpolarized gas. The dotted lines (top) indicate the small magnetic field in the chamber that provides an alignment axis for the optical pumping and polarization. The $\lambda/4$ plate circularly polarizes the laser light. The optical pumping (bottom left) preferentially populates one Rb electronic state that then exchanges with the He nucleus (bottom right)

Figure 2 A commercially manufactured optical pumping and spin exchange system showing the Helmholtz coils, the laser optics, and control computer and illustrating that hyperpolarization equipment can be compact enough to fit in laboratory or hospital environments

way or research laboratory. Such systems are presently based on a 120 W AlGaAs diode laser. An optical chamber roughly 220 cm³ in volume contains about 8–10 atm ³He gas and a few milligrams of Rb metal. The chamber is heated to around 200 °C to increase the Rb vapor density to about 1×10¹⁵ atoms cm⁻³ (~1 ppm of the ³He concentration). Optical pumping under these conditions results in a time constant for polarization build-up of about 4 h and a saturation polarization level of about 45%. Thus, 2 l of highly polarized ³He gas can be produced in about 4 h.

2.2.2 Polarization of ¹²⁹Xe

Polarization of ¹²⁹Xe through the OPSE technique has been studied since the first demonstration by Grover in 1978.¹⁹ However, unlike polarized ³He, where its utility as a nuclear target has stimulated substantial efforts towards its production in large quantities, high-volume production of polarized ¹²⁹Xe was not pursued until its potential importance in MRI was realized.¹³ Predicted polarization levels and production rates for ¹²⁹Xe are not too different from those achievable with ³He. Both gases should be able to be polarized to near 100% with production rates of the order of liters per hour, depending on available laser power. However, practical implementations for polarizing ¹²⁹Xe are somewhat more complex.

One approach has been to polarize ¹²⁹Xe in batch mode, as described for the ³He process.²⁰ With this technique, polarizations of 7.5% have been realized for batches of 157 cm³. Unfortunately, batch techniques, while simpler to implement, are limited in the ultimate achievable polarization and production rate. An alternative scheme is to polarize a dilute mixture of ¹²⁹Xe in a ⁴He carrier gas in a continuous flow method with subsequent cryogenic extraction and storage of hyperpolarized solid ¹²⁹Xe.²¹ This technique is being explored by several research teams and for the commercial system mentioned previously. Polarization levels as high as 45% have been observed in the flowing gas stream. However, after cryogenic accumulation and thawing, the highest observed

polarization level has been 20% for a 250 cm³ batch.²² Undoubtedly, with continued development efforts, ¹²⁹Xe polarization techniques will soon reach the level of robustness that has been achieved with ³He systems.

2.2.3 Polarized Gas Storage, Transport and Supply

To date, most MRI studies using hyperpolarized ³He or ¹²⁹Xe have been performed with the polarizer in close proximity to the MR magnet. One notable exception has been the early imaging work performed at Heidelberg with polarized ³He produced at Mainz and subsequently transported roughly 100 km to the imaging site.²³ Such demonstrations emphasize the unique properties of polarized gases, which could allow polarized ³He and ¹²⁹Xe to be produced in centralized locations and then transported to hospitals or imaging facilities on an as-needed basis, similar to what now occurs with radioisotopes.

Polarized ³He relaxation times in excess of 100 h have been observed in specially coated vessels.²⁴ The longest reported observed relaxation time was 171 h in a specially prepared, sealed aluminosilicate cell containing 4 atm ³He.²⁵ This same study showed that the theoretical limit to the ³He relaxation time imposed by ³He–³He collisions is 750 h at 1 atm. Such polarization lifetimes are more than sufficient to give serious consideration to centralized distribution of polarized ³He. However, considerable development effort is still required to achieve such long relaxation times routinely.

Long gas phase relaxation times are more difficult to achieve for ¹²⁹Xe. The ¹²⁹Xe–¹²⁹Xe relaxation mechanism is quite efficient, limiting the gas phase relaxation time to 56 h at 1 atm.²⁶ However, more problematic is that the much stronger adsorption energy for Xe on surfaces makes relaxation resulting from interactions with the container walls much more effective. Typical gas-phase relaxation times of ¹²⁹Xe are 20–60 min. Relaxation times as long as 4 h have been observed in specialized high-purity vessels, but this has not been reproducible. It will require a committed research effort to realize gas-phase relaxation times of even tens of hours in the foreseeable future. Fortunately, it has been shown that ¹²⁹Xe can be frozen and thawed without substantial loss of polarization.²⁷ The relaxation time of solid ¹²⁹Xe at 77 K (liquid N₂) is a modest 2–3 h; however when ¹²⁹Xe is cooled to 4.2 K (liquid He), relaxation times as long as 12–20 days have been observed.²⁸ While significant engineering challenges still lie ahead in distributing polarized gases, early results are promising.

The world supply of these gases is of tremendous importance to the future viability of this technology. For example, ³He is not naturally abundant in substantial quantities. Its primary source is through the decay of tritium in nuclear weapons. The total available supply is classified but is not substantially larger than a few tens of thousands of liters per year. Therefore, the true commercial success of imaging with hyperpolarized ³He will require both a small dose of ³He to be used for each imaging scan (~100 cm³) and potentially some recycling of the exhaled gas. Recycling of ³He should be feasible with high efficiency, allowing as much as 95% of each administered dose to be recovered. The supply of Xe gas is essentially infinite, which makes Xe a good long-term prospect. However, the ¹²⁹Xe isotope is only 26% naturally abundant, and enrichment may be desired to increase image SNR. However, while natural abundance Xe costs only about US \$10 per liter, present prices (1999) of 80% enriched ¹²⁹Xe are much

more expensive and are unlikely to be reduced in cost based on present technology.

3 IMAGING OF POLARIZED GAS

3.1 System Requirements

3.1.1 Magnetic Field Strength

Hyperpolarized gas imaging can be accomplished on nearly any MRI system that meets the requirement of being able to operate at a resonant frequency that is very different from the proton Larmor frequency for the field strength of the system. Such systems are often called ‘broadband’ systems. Alternatively, for a fixed frequency (narrowband) system, it may be possible to change the magnetic field strength so that the fixed frequency is the resonant frequency of the gas. This is not likely to be the case for most MR systems since the resonant frequency of ^3He and ^{129}Xe (48 MHz and 17 MHz, respectively, at 1.5 T) are well below that of hydrogen (64 MHz at 1.5 T). Therefore, the magnetic field would have to be increased when most systems are usually operating at the maximum field for which they were designed.

A variant of the broadband system is the ‘multinuclear’ design, for which certain, fixed frequency bands are allowed in addition to the hydrogen band. A 1.5 T system might have frequencies available for ^{19}F (60 MHz), ^{31}P (26 MHz), ^{13}C (16 MHz), and ^2H (10 MHz) as well as the ^1H frequency.²⁹ For this type of system, it may be possible to lower the main field to have the gas resonate at one of these lower frequencies.

The choice of field strength is usually guided by the fact that the SNR of conventional MRI increases nearly linearly with the magnetic field for constant bandwidth and full relaxation.³⁰ For hyperpolarized gas, the magnetization does not depend on the magnet and, therefore, the considerations in the choice of field strength are altered. The origin of the linear magnetic field dependence for conventional SNR is the increase in the polarization as field increases. The transverse magnetization created by rf pulses is that much larger, leading to larger induced voltages in the rf coil. The increased frequency also contributes to the increased voltage, but its effect is canceled by the increased noise voltage at higher frequency. The conclusion from these considerations is that the SNR for hyperpolarized gas imaging should be independent of the main magnetic field strength.¹⁰

This result could be very advantageous for imaging tissues such as the lung or bowel since tissue–air interfaces distort the local magnetic field through the magnetic susceptibility difference at the interface. The magnetic field distortion causes rapid

dephasing of the MR signal, leading to poor SNR for conventional imaging in the lungs.³¹ The susceptibility-related dephasing is more rapid at high magnetic fields. Therefore, the use of hyperpolarized gas for lung imaging may be better at lower magnetic fields. While most commercial MRI systems use a magnetic field of 1.0–1.5 T, there are many systems in the 0.1–0.5 T range. Unfortunately, these lower field systems usually operate at a fixed (hydrogen) frequency.

3.1.2 Radiofrequency System and Coils

For broadband MR systems, the main considerations for the equipment are a suitable rf coil and associated preamplifier. For truly broadband systems, the preamplifier may not require modification, but multinuclear systems often have tuned preamplifiers that do not operate at other frequencies. Usually, for research groups, it is not too difficult to construct rf coils and obtain preamplifiers that are compatible with an MR system. These rf coils can often be constructed out of readily available materials to existing designs,³⁰ although certain expensive equipment, such as a network analyzer, must be available for tuning and troubleshooting. However, until manufacturers of commercial MR systems offer ^3He and ^{129}Xe capability, hyperpolarized gas imaging will remain a research tool.

For convenience, it is useful to consider a dual-tuned coil that can image at the desired gas frequency and at the hydrogen frequency so that conventional images can be obtained for comparison and reference. On MR systems that have a built-in body-sized rf coil, it is often possible to obtain conventional images with this coil and have a single tuned, smaller coil for gas imaging that is ‘blocked’ or detuned so as not to interfere with the conventional imaging. Such arrangements avoid possible subject movement during coil changes. Coil performance is often compromised when it has two resonant frequencies; therefore, the best choice may be a single tuned coil that is proton blocked. Another advantage of single tuning is that a circularly polarized or ‘quadrature’ design can be used.³² This is hard to achieve for dual-tuned coils and gives nearly the same performance as a so-called ‘phased array’ coil.^{33,34}

3.2 Helium MRI

3.2.1 Gas Diffusion Solubility, and Lifetime Considerations

Table 1 gives some of the physical characteristics of ^3He and ^{129}Xe . Helium-3 has very low solubility in blood or tissue and, therefore, is considered mainly suitable for air space imaging such as in the lung, bowel, nasopharynx, or sinuses. While ^3He is inert and mixtures of ^4He and oxygen have been breathed in diving mixtures for many years, there are still medical regulatory issues with both ^{129}Xe and helium since, at

Table 1 Physical data for ^3He , ^{129}Xe and O_2

Gas	Density (g l^{-1} at STP)	Gyromagnetic ratio (MHz T^{-1})	Solubility			T_1 (s, in lung)
			Blood	Brain	Fat	
^3He	0.133	32.4	0.01	–	0.02	28.8
^{129}Xe	5.75	11.8	0.15	0.17	1.9	31.3

Solubility: Oswald solubility at 37 °C (ml gas per ml fluid).³⁵ Value for T_1 from Moller et al.³⁶

Figure 3 The decline in longitudinal magnetization for a hyperpolarized gas as a function of the rf pulse number for different flip angles (α). As the flip angle increases, the polarization is used up more quickly since gas polarization does not recover toward the initial value but rather to an extremely small equilibrium value

least in the USA, they fall under the FDA authority, which regulates medical gases as drugs.

Helium-3 diffuses rapidly but appears, from imaging experiments to date, to be reasonably well confined by biological membranes. Its lifetime is shortened considerably when mixed with oxygen.³⁷ As an example, the lifetime (T_1) of ^3He when mixed with 21% oxygen is only about 11 s while it is of the order of 1 h in its prepared state. Therefore, the primary considerations in imaging hyperpolarized gas are the need to perform the imaging as rapidly as possible and the fact that the magnetization does not recover to any useful degree toward the large initial magnetization. This leads to a ‘use it or lose it’ approach to MR pulse sequence design. There are two types of pulse sequence that have been used for ^3He imaging: gradient-echo, Fourier phase-encoded imaging (GRE)³⁸ and projection-encoded imaging (PE).³⁹ Both methods require a number of encoding steps, each step preceded by a rf pulse. After every rf pulse of flip angle α , the magnetization is reduced by a factor of $\cos \alpha$. The reduction of magnetization is illustrated in Figure 3 for 128 consecutive rf pulses (a typical number for an MR scan sequence) for flip angles ranging from 1 to 10°. For such constant flip angle scans, it is easy to calculate the flip angle that will reduce the magnetization to zero by the end of the scan. The graph shows that the magnetization is largest at the beginning of the scan and decreases monotonically.

It has been shown that the acquired signals that correspond to the low spatial frequencies of the image are responsible for most of the image intensity value and, thus, the image SNR.⁴⁰ This leads to the idea of the use of ‘centric’ phase encoding for GRE methods such that the low spatial frequency values are acquired at the beginning of the imaging to obtain the highest SNR value. The gradual lowering of the signal can lead to a loss of resolution in the final image with the centric scheme since the high spatial frequencies of the image have a reduced amplitude. Consequently, another method has been suggested in which the flip angle is varied: using a smaller flip angle at the beginning and leading to a larger flip angle at the end.⁴¹

The PE methods usually require a larger number of encodings for an image than an equivalent GRE approach because they oversample the low spatial frequencies. The larger number of encodings lead to the use of smaller flip angle, which can reduce SNR. However, the oversampling of the low frequencies allows the use of normalization strategies to compensate for signal changes during the scan. Also, PE methods can achieve a shorter TE than GRE and show fewer motion artifacts.

3.2.2 Animal Lung Imaging of ^3He

Early ex vivo ^3He images in guinea pigs were made with the GRE pulse sequence after inflating the lungs with the polarized ^3He .⁴² Subsequent in vivo studies have concentrated on the PE method.^{36,43–45} An advantage of this method is that the first points of each signal after an rf pulse sample the average lung intensity, thus allowing high-time resolution studies of gas dynamics. In addition, for small animals, the imaging gradients in GRE sequences can cause large diffusive signal loss; consequently the PE method is more easily employed for diffusion evaluation.

The great advantage of animal studies is that control can be exerted over the flow of gas and the mixture of gas to the lung as well as the consumption of smaller amounts of gas. This allows the study of how the flow of gas and rf flip angle interact to emphasize different parts of the lung. As the gas flows into the trachea, it experiences several rf pulses on its way to the lung periphery. Large rf flip angles use up the magnetization before the gas reaches the periphery, small angles allow the gas to still give signal at the periphery, as shown in Figure 4.

Animal studies have also shown that the gas has a very short T_2^* in the lungs, emphasizing the need for very short TE values, as illustrated in the figure. While T_1 has been estimated in human and animal lungs to be 30 s, the T_2^* is only about 10 ms.⁴⁶ As illustrated in Figure 5, the rapid decay of magneti-

Figure 4 Images of hyperpolarized ^3He in a guinea pig’s lungs for different flip angles. The gas polarization level was 7%. Images were acquired with a projection-encoded pulse sequence with TR 5 ms, FOV 48 mm, 800 projections, in-plane resolution 188 μm ; the slice thickness contains the entire lung. Small flip angles emphasize the lung periphery while large flip angles emphasize the airways. (Reproduced by permission of Williams & Wilkins Press from Chen et al.⁴⁴)

Figure 5 Images of hyperpolarized ^3He in a guinea pig's lungs for two different TE values. The gas polarization level was 20%. Images were acquired with a projection-encoded pulse sequence with TR 5 ms, FOV 48 mm, 800 projections, in-plane resolution $188\ \mu\text{m}$, and 5 mm slice thickness. The left image has an acquisition delay or TE of 1 ms, while the right image has a value of 5 ms. Even modest TE values (greater than 1 to 2 ms) can show undesirable signal loss that may be mistaken for lung abnormalities (Images courtesy of X. J. Chen and G. A. Johnson, Center for In Vivo Microscopy, Duke University Medical Center)

zation can make ventilated regions appear not to be receiving gas.

Imaging of gases also must take into account their much larger diffusion coefficients compared with liquids. Measurement of ^3He gas in a sealed container⁴⁷ gives values of $1.8\ \text{cm}^2\ \text{s}^{-1}$ while that of water is $2.1 \times 10^{-5}\ \text{cm}^2\ \text{s}^{-1}$. As a result, a gas atom will move several millimeters in 10 ms (several pixels in the image), while a water molecule moves only a fraction of that distance. The gas is likely to exhibit restricted diffusion in lungs, thus opening up the potential for use of diffusion changes to indicate progressive deterioration of lung structure.⁴⁸

The basic conclusions that have been drawn from animal studies are that the image intensity is proportional to the amount of gas inhaled and the level of polarization: T_1 is of the order of 30 s, T_2^* is of the order of 10–20 ms at 2.0 T, and the gas diffusion is likely to be affected by lung structure.

3.2.3 Human ^3He Lung Imaging

Imaging human lungs is reasonably straightforward compared with animal imaging because the human subject can cooperate with the procedure. This removes much of the difficulty of preparing and supporting animal subjects. While animal imaging can produce images over the course of several breath-holds, the human images must usually be accomplished in a single breath-hold. As a practical matter, most polarization systems produce a limited supply of gas. While 1 l of hyperpolarized ^3He is sufficient for several animal studies or many breaths for a guinea pig, it is just enough for one or two human breath-holds. Smaller quantities can be used as technology improves the level of polarization of the ^3He . Presently, studies have been performed with gas that has up to a 45% polarization and a volume of 200–600 ml,^{23,49,50} although good studies can also be achieved with 10% polarization and a larger gas quantity.⁵¹ Most of the human studies to date have been performed with the GRE method since it is readily available on most human MRI systems, while PE methods require pulse sequences and image reconstruction methods that are not usually commercially available.

A set of images of the lungs of a human volunteer are shown in Figure 6. The dark lines in the images indicate blood vessels in the lung. Such images are encouraging since they show good ventilation in this healthy volunteer. Images of the lungs of a subject with cystic fibrosis are shown in Figure 7. Another subject, who has received a lung transplant and is experiencing early rejection symptoms, is shown in Figure 8.

Early human imaging with ^3He shows clearly altered lung ventilation patterns in disease states compared with that in healthy subjects. However, it is yet unproven to what degree this may be useful in following disease progress. Studies of healthy volunteers have shown that even relatively benign processes such as allergy or colds can show transient ventilation differences with ^3He imaging, leading to concerns that the method may be 'too sensitive'. As with any new medical technique, it requires controlled clinical trials to establish the eventual medical utility of this new capability.

3.3 MRI and MRS with ^{129}Xe

Xenon-129 potentially has even greater promise than ^3He since it has higher solubility (about 15%) in blood and tissue (Table 1). Early spectroscopic measurements have shown that the ^{129}Xe that has moved from the lung air space to the blood has nearly a 200 ppm chemical shift, as shown in Figure 9.^{52,53} There appear to be four distinguishable chemical shifts, owing to (a) the gas phase in the lungs (0 ppm), (b) the alveolar tissue phase (200 ppm), (c) the plasma phase (192 ppm), and (d) the red blood cell phase (213 ppm). There is some controversy as to the interpretation of the peak at 200 ppm, with some investigators suggesting that it results from the effect of lung tissue-induced B_0 inhomogeneity on the other nearby peaks. In any case, this rich chemical shift structure should afford many possibilities for study of lung structure and function.

While ^{129}Xe diffuses more slowly than ^3He and, therefore, may imitate the flow of air more closely, it has two major difficulties for use as an imaging agent. It has a much lower gyromagnetic ratio than helium, which leads to the requirement for more rf power during excitation (for equal pulse time) than for helium and to lower SNR for equal spin density. Also, ^{129}Xe acts as an anesthetic above concentrations of 70%, with noticeable effects (light-headedness, slowed reaction) at concentrations above 30% in humans.^{54,55} Therefore, while natural abundance, nonpolarized xenon has been used for short periods in computed tomography brain blood flow imaging⁵⁶ at a concentration of 39%, its use in humans must take into account such effects. It is interesting to note that because of its prior medical use, natural abundance xenon may have a simpler regulatory environment than the more inert ^3He .

In addition to lung imaging, ^{129}Xe has also been proposed as a brain or cardiac perfusion agent because of blood solubility. Investigators have shown ^{129}Xe signals from the brains of human subjects who breathe hyperpolarized ^{129}Xe .¹² Calculations have been published which indicate that a signal can be obtained from blood perfusion that is approximately 2–4% of the proton brain signal.^{57,58} This is comparable with noninvasive arterial spin labeling approaches for perfusion measurement⁵⁹ and should have the advantage of having no 'background' signal to subtract. However, for repeated

Figure 6 Images of hyperpolarized ^3He in the lungs of a healthy human volunteer. The gas polarization level was 10% and the quantity was 1.5 l. Images were acquired with a gradient-echo pulse sequence with TR 11 ms, TE 2 ms, FOV 36 cm, flip angle 6° , slice thickness 1 cm, 128 phase encodings, and in-plane resolution 1.7 mm. Healthy lung parenchyma shows a uniform intensity with dark lines along the course of blood vessels

Figure 7 Images of hyperpolarized ^3He in the lungs of a subject with cystic fibrosis. The gas polarization level was 15% and about 0.75 liter was inhaled. Images were acquired with a gradient-echo pulse sequence with TR 11 ms, TE 2 ms, FOV 36 cm, flip angle 6° , slice thickness 1 cm, 128 phase encodings, and in-plane resolution 1.7 mm. The lung shows a patchy appearance

Figure 8 Images of hyperpolarized ^3He in the lungs of a subject after a single-side lung transplant. The gas polarization level was 15% and about 0.75 liter was inhaled. Images were acquired with a gradient-echo pulse sequence with TR 11 ms, TE 2 ms, FOV 36 cm, flip angle 6° , slice thickness 1 cm, 128 phase encodings, and in-plane resolution 1.7 mm. The left side of the image is the transplanted lung, showing more ventilation than the right-side (native) lung

measures, the noninvasive nature of arterial spin labeling approach may prevail over repeated breathing of ^{129}Xe .

In addition to providing chemical shift data, the animal studies have shown that the T_1 of ^{129}Xe in the lung is approximately 30 s.^{36,53} Therefore, single breath-hold studies should be able to be accomplished in a manner similar to ^3He studies by using GRE pulse sequences with short echo times.

Figure 9 Spectrum of ^{129}Xe in the chest of a dog acquired using enriched (80%) ^{129}Xe , showing the gas phase and the dissolved phase peaks. (Spectrum courtesy of K. D. Hagspeil, and J. Mugler, University of Virginia)

Because of the lower gyromagnetic ratio and lower practical polarizations (up to 20%) reached to date, images made this way show lower resolution and SNR. However, as the images in Figure 10 show, it is still possible to make very good images of the lung with the lower costing, natural abundance hyperpolarized ^{129}Xe .

4 CONCLUSIONS

Hyperpolarized gas imaging provides a tremendous new opportunity to visualize the airways and air spaces in the lungs

Figure 10 Images of natural abundance (26% ^{129}Xe) hyperpolarized ^{129}Xe in the lungs of an anesthetized beagle. The gas polarization level was 10% and the quantity was 160 ml. Images were acquired with a gradient-echo pulse sequence with TR 300 ms, TE 6 ms, FOV 50 cm, flip angle 8° , slice thickness 3 cm, 128 phase encodings, and in-plane resolution 0.4 cm

as well as in body cavities such as the bowel or nasopharynx. Possibilities also beckon for use in measuring brain perfusion or as vascular contrast agents. The work to date in animals and humans has shown that the technique is easily performed given the proper equipment. Some commercially available MRI systems can provide the necessary ability to tune to the ^3He or ^{129}Xe resonant frequency. Coil development is straightforward for small animal systems and well within the typical research laboratory capability. Coil design for human systems may be best done by commercial coil companies or the MRI manufacturers since they should be created under strict safety standards and must interface properly with manufacturers' safety equipment. Development of custom equipment for gas polarization can be done in research laboratories with equipment that can be purchased commercially.

Early results show that the techniques are sensitive to lung pathology and that gas signals can be obtained from the brain and blood, but much work is yet to be done in controlled trials to demonstrate sensitivity, specificity, and cost-effectiveness.

Lung and Mediastinum: A Discussion of the Relevant NMR Physics

David C. Ailion

University of Utah, Salt Lake City, UT, USA

1 INTRODUCTION

Of all organs in the human body, lung is one of the most difficult to image. This difficulty has three primary causes: (1) lung has a relatively low water density (about 20%) compared to that of other organs; (2) the NMR lineshape in lung is inhomogeneously broadened by susceptibility effects¹ (see *Susceptibility and Diffusion Effects in NMR Microscopy* and *Susceptibility Effects in Whole Body Experiments*) arising from the existence of air–water interfaces associated with the alveoli; and (3) its NMR image is subject to motional artifacts² arising from the asynchronous motions of the heart and chest wall. In spite of these difficulties, considerable progress has been made in recent years in developing imaging techniques that minimize errors due to the susceptibility and motional effects. Furthermore, significant advances have been made in measuring the parameters³ (e.g. linewidth, relaxation times, diffusion constants) that characterize the NMR behavior of lung and in understanding their underlying physical mechanisms. The techniques used in these studies are also currently being used in medical applications³ to determine the state of normal and injured lungs (see *Lung and Mediastinum MRI*). The current status of NMR methods for studying lung tissue (including medical applications) have been reviewed.⁴ Techniques for imaging the gas-filled regions are described briefly at the end of this article (see also *Hyperpolarized Gas Imaging*).

An explanation of the physical origin of the inhomogeneous broadening in lung is given and is followed by a discussion of the present state of our understanding of the mechanisms responsible for the various NMR parameters: lineshape, spin–spin relaxation time (T_2), spin–lattice relaxation time (T_1), and diffusion constant (D). Finally, techniques that are currently used to investigate and image lungs are presented.

2 INTERNAL INHOMOGENEOUS LINE BROADENING IN LUNG

2.1 Free Induction Decay in Lung

Most biological tissues are characterized by a free induction decay (FID) of a duration of the order of several hundred milliseconds. In contrast, lung has a much shorter FID (broader NMR line), the value of which (about 2–4 ms)⁵ depends on B_0 and the state of inflation of the lung. Since this very short FID is much less than the inhomogeneity in B_0 in most magnets, it must arise from a mechanism internal to lung. The signal loss

due to this mechanism has been shown to be reversible (corresponding to an inhomogeneous broadening), since the application of either a 90–180° pulse sequence or a Carr–Purcell sequence⁶ recovers the signal in an echo. The fact that the FID is shorter in inflated lungs than in normal or degassed (airless) lungs⁵ suggests that the line broadening is associated with the presence of air–tissue interfaces at the boundaries of the alveoli of lung. Similar measurements⁵ performed on an alumina/water ($\text{Al}_2\text{O}_3/\text{H}_2\text{O}$) slurry consisting of 5 μm diameter alumina particles in water also showed a short FID that can be recovered in an echo (see Figure 1). Since alumina has a bulk diamagnetism that is approximately twice that of water, these results suggest that the broadening arises from the presence of interfaces between materials having different magnetic susceptibilities (air–tissue in lung, and alumina–water in the slurry). The decay time of the FID owing to internal inhomogeneous broadening mechanisms, such as these susceptibility effects, is called T_2' .

2.2 Theoretical Models for Calculating NMR Lineshapes in Lung

2.2.1 Spherical Shell Model

The confirmation that susceptibility effects at the water–tissue interfaces are indeed responsible for the inhomogeneous line broadening and corresponding shortening of the FID in lung came from a combination of model calculations and phantom experiments.¹ In all these calculations, lung tissue is treated as pure water, having some predetermined geometrical shape. For instance, consider the well-known behavior of a diamagnetic sphere (of, for example, water) in an otherwise uniform applied magnetic field B_0 . Calculations¹ of the magnetic induction B using Maxwell's equations⁷ predict a shift in the value of the magnetic induction but not a spread in its values. This can be seen from Figure 2(a), in which the lines of force within the sphere are parallel, but have a slightly different density from those outside the sphere and far from it. The magnetic induction shift caused by a uniform sphere of

Figure 1 FIDs of inflated lung, degassed lung, and an alumina/water slurry

Figure 2 (a) Lines of force for sphere of water in an otherwise uniform magnetic field; (b) lines of force for spherical shell of water in an otherwise uniform magnetic field. (Reproduced by permission of Pergamon Press from D. C. Ailion, *Magn. Reson. Imaging*, 1992, **10**, 799)

radius a and relative permeability μ ($= 1 - \Delta\mu$) is given to first order by¹

$$\Delta B = -2\Delta\mu B_0/3 \quad \text{if } r < a \quad (1)$$

and

$$\Delta B = \Delta\mu B_0 a^3 (r^2 - 3z^2)/3r^5 \quad \text{if } r > a \quad (2)$$

where $\Delta\mu$ represents the difference in relative permeability of the diamagnetic sphere and air (about 9 ppm for water), and r is the distance of the field point from the center of the sphere. The field shifts can also be calculated for a diamagnetic spherical shell by simply superimposing the results for two concentric spheres of different radii and different permeabilities.¹ In this case, there will be a spread in the values of B , since the lines of force are no longer precisely parallel [see Figure 2(b)].

In fact, the flux density B will be reduced for those portions of the shell (top and bottom) that are approximately parallel to the field, but will be unaltered for those regions (middle) that are perpendicular to it.

This spread in B will result in a broadening of the NMR linewidth. The existence of this broadening has been observed experimentally in a spherical shell phantom consisting of two concentric glass spheres with water filling the space between them.¹ Excellent agreement was obtained between the measured and theoretical lineshapes for this phantom.

2.2.2 Spherical Foam Model

A better model [Figure 3(a)] for the alveolar region than that of a single spherical shell consists of a lattice containing spheres of air with water in between, with each sphere of air (representing an alveolus) centered on a different lattice point. Calculations using this model¹ showed that the linewidth increases (though not precisely linearly) with the air percentage of the total volume. Furthermore, by calculating the inverse Fourier transform of the lineshape, the FID time constant T_2' was determined to be 3.4 ms for 70% air at 40 MHz, which is in excellent agreement with our measurements on lung.

2.2.3 Wigner-Seitz Model

A disadvantage of the spherical foam model is that it can not be used for large air/water ratios, since the spheres will touch and the model will break down when the percentage of air reaches 74%. A better model has been employed in which the spherical air spaces are replaced by space-filling Wigner-Seitz polyhedra⁸ [Figure 3(b)], with the water occupying the interfaces between the polyhedra. This model can be improved [Figure 3(c)] by rounding the corners of the polyhedra, so that the shape corresponds more to that of actual alveoli, and by thickening their walls, in order to accommodate any desired air/water ratio from 0 to 100%. This model gives a slightly asymmetric lineshape, which has been observed experimentally in isolated rat lung.⁹ Figure 4 shows a comparison between a

Figure 3 Two-dimensional cross-section of various models of the alveolar region: (a) spherical foam; (b) Wigner-Seitz foam; (c) modified Wigner-Seitz foam with thickened boundaries and rounded corners. In the Wigner-Seitz models, the air is in the polyhedral spaces, and the water (representing alveolar wall tissue) is in the boundaries

calculated Wigner–Seitz lineshape (for 90% air volume) and one measured from a voxel in the outer (alveolar or parenchymal) region of an excised isolated rat lung.

2.2.4 Long Cylinder Model

A very different model (cylindrical)⁹ is needed for the central (mainly nonparenchymal) region of the lung, which contains bronchi and large blood vessels. This model predicts a symmetric, but shifted, NMR line the shift of which depends on the orientation of the cylinder relative to the magnetic field. The shift is largest for the cylinder's long axis parallel to B_0 and smallest for the long axis perpendicular to B_0 . In a similar comparison⁹ between calculated and experimentally measured NMR lineshapes from the central region of an isolated excised rat lung, the experimental shape can be fit as a superposition of parenchymal (Wigner–Seitz) and nonparenchymal (cylinder) lines, suggesting the presence of both kinds of structure in the central region. These results suggest that regional lineshape measurements can distinguish different types of geometry in rat lung.

2.2.5 Other Geometries (Slabs, Cubes, Cubical Shells)

Because of the obvious sensitivity of the NMR lineshape to water geometry, theoretical investigations have been extended to other types of water geometry^{10,11} (slabs, cubes, cubical shells). A comparison of experimental measurements with theoretical lineshapes is shown for various geometrical phantoms in Figure 5.

For the slabs, as with the cylinders, the field shift depends on the orientation of the slab relative to the magnetic field direction, being maximum (about -9 ppm) for B_0 parallel to the face of the slab and minimum (close to zero) for B_0 perpendicular to it. For cubes, the field shift is intermediate (about -6 ppm) between these extremes and is comparable to that for a solid sphere. However, unlike the sphere, the field inside a cube is not uniform, so that the cube produces some line broadening. The cubical shell for which B_0 is perpendicular to one face has four faces which are parallel to the field and two

that are perpendicular to it. These features appear in the figure. In summary, it appears that the NMR properties of water can be categorized on the basis of the aspect ratio of the water containing region in terms of 'thick' water (resulting in a narrow linewidth) and 'thin' water (resulting in a broad linewidth whose field at the peak depends on the orientation of the thin water relative to the magnetic field).

3 RELAXATION TIMES IN LUNG

Knowledge of the transverse (T_2) and longitudinal (T_1) relaxation times are important not only in optimizing an NMR image but also in determining the underlying structure and dynamics (see *Relaxation Measurements in Imaging Studies* and *Relaxometry of Tissue*).

3.1 T_2 Behavior

3.1.1 Hahn Echo

A common way to measure the spin–spin relaxation time in a liquid is to apply a 90° pulse, followed a variable time τ later by a 180° pulse, thereby producing an echo (the so-called 'Hahn echo') at 2τ , whose amplitude decreases (in principle, exponentially) with a time constant T_2 . However, if the spins can diffuse without restriction in a magnetic field gradient (either internal or external) then the decay will not be exponential, but will be given by⁶

$$M(2\tau)/M(0) = \exp(-2\tau/T_2) \exp[-2(\gamma g)^2 D \tau^3/3] \quad (3)$$

where γ is the gyromagnetic ratio, g is the magnetic field gradient, and D is the diffusion constant. For sufficiently rapid diffusion in large gradients, a measurement of the Hahn echo time constant will provide information about the nature of the diffusion, but will not reflect the underlying T_2 .

3.1.2 The Carr–Purcell–Meiboom–Gill Technique

Carr and Purcell developed a one-shot technique⁶ for eliminating the τ^3 term from the decay. This technique, later modified by Meiboom and Gill to minimize errors due to inaccurate pulse widths, consists of following the initial echo by a series of equally spaced echo-producing 180° pulses. By making the time between these pulses sufficiently short, the τ^3 term can be virtually eliminated, thereby providing a measurement of the underlying T_2 .

3.1.3 Diffusion Measurements in Lung

A comparison of the Hahn decay with the Carr–Purcell–Meiboom–Gill (CPMG) decay measured in excised rat lung (Figure 6) reveals that the Hahn decay is much shorter than the CPMG, indicating the presence of significant diffusion in internal gradients, probably arising from the alveolar air–tissue interfaces.

The Hahn decay time provides a measure of the product Dg^2 , but not of either parameter alone. However, by applying large known pulsed gradients g_a , D can be determined from a plot of $\log [M(2\tau)/M(0)]$ versus g_a^2 . Because of the presence of large internal magnetic field gradients, special techniques^{12,13} should be employed to separate the effects of the internal and

Figure 5 Comparison of theoretical (....) and experimental (—) NMR lineshapes for various water geometries. (a) Water slab (thickness 0.10 in. (2.5 mm)) perpendicular to B_0 . (b) Water slab parallel to B_0 (thickness 0.10 in. (2.5 mm)). (c) Water cube with face perpendicular to B_0 (thickness 1.0 in. (2.5 mm)). (d) Cubical water shell (thickness 0.125 in. (3.2 mm)) with face perpendicular to B_0 . (Reproduced, with modification, by permission of Pergamon Press from D. C. Ailion, *Magn. Reson. Imaging*, 1992, **10**, 799)

external gradients. One of the approaches¹² uses pulsed field gradients (PFG) arranged (e.g., in a 13-interval sequence¹⁴) to eliminate the effects of the internal gradients on the magnetiza-

Figure 6 Normalized spin echo amplitude versus echo time for passively collapsed lung at 1.9 T. (Reproduced by permission of the Society of Magnetic Resonance in Medicine from H. Kolem, C. Goodrich, K. Ganesan, D. C. Ailion, A. G. Cutillo, S. Chen, A. H. Morris, S. Shioya, and S. Watanabe, in *Proc. VIIIth Ann Mtg. Soc. Magn. Reson. Med.*, New York, 1989, p. 685)

tion decay. The other approach¹³ uses extremely large (~ 0.2 – 1 T/cm) static magnetic field gradients (SFG) obtained either from the fringe field of superconducting magnets or from specially wound anti-Helmholtz magnets.¹⁵ Since the applied gradient g_a cannot be conveniently varied with this technique, a stimulated echo sequence^{13,15} is used in which the magnetization decay is monitored (and D is determined) by varying the time τ between the first two 90° pulses. Because of the extremely large size of the external gradient, dephasing through the internal gradients and T_2 can safely be neglected. By varying the time between the second and third pulses of the stimulated echo sequence, the time dependence of D can be measured. Even for restricted diffusion, the molecules will appear to be diffusing freely over times short compared with the mean time for a molecule to reach the restricting boundaries; however, for much longer diffusion times, the molecules' spatial displacements may be restricted, resulting in a change in the time dependence of D . The mean distance separating the barriers restricting the diffusion can be estimated from measurements of the time at which this crossover from 'free' to 'restricted' diffusion occurs.¹³

Measurements of D in excised rat lungs^{12,13} by both these techniques indicate the presence of at least two diffusion coeffi-

cients. Imaging measurements of D using the 13-interval sequence were performed¹² in the central (mainly nonparenchymal) and outer (parenchymal) regions in excised intact rat lungs and compared with the results of separate nonimaging measurements on lung fragments taken from the central and outer regions. These experiments indicate that both diffusion components are present in each lung region, but perhaps in differing proportions, with the more rapid component being more significant in the central lung region and the slower component being relatively large in the alveolar region.¹² Similar measurements on edematous rat lung indicate an increase in the magnetization associated with the more rapid decay even in the alveolar region, suggesting that edema is characterized by an increase in the more rapidly moving (presumably freer) water. Since the relative size of the larger D is still an order of magnitude smaller than that of free water, it can be concluded that even the diffusion in the central portion of the lung is restricted. Measurement of the time dependence of D in fragments from the alveolar region of excised rat lungs using the large SFG approach indicates a crossover from 'free' to 'restricted' diffusion corresponding to several micrometers.¹⁴ A careful analysis of the data indicates that the shape of the crossover may be explained by a distribution of restriction sizes extending up to 18 μm but with a mean value of 3.7 μm . This value corresponds quite well to the known thickness of epithelial cells in the alveolar walls, which is typically approximately 3 μm , suggesting this to be the primary origin of restricted diffusion in the alveolar portion of the lung.

3.1.4 CPMG T_2 Measurements in Lung

CPMG T_2 measurements¹⁶ in rat lung reveal a multiexponential decay with a time constant increasing gradually from a few to several hundred milliseconds. This decay can be fitted by four time constants. Time course measurements of these components on a lung which is gradually drying out reveal that the longest T_2 component disappears completely before the next starts to decrease, and the second longest disappears completely before the next decreases, and so on. These results suggest that the longer T_2 components are associated with less tightly bound water and the short T_2 components with more tightly bound water. Pulsed gradient measurements of the diffusion constant associated with each T_2 component show a strong correlation between T_2 and D , with the longer T_2 components corresponding to the more rapidly diffusing (larger D) molecules.

3.2 T_1 Behavior

As with T_2 , the spin-lattice relaxation time T_1 can provide useful information about the microscopic environment of a spin. In contrast to T_2 , which is multiexponential, T_1 is monoexponential in lung. Imaging measurements¹⁷ have shown that T_1 varies regionally in lung.

3.2.1 Frequency Dependence of T_1 in Lung

In general, the Larmor frequency dependence of T_1 is sensitive to the microscopic relaxation mechanism. Accordingly, measurements of T_1 as a function of frequency can often be used to eliminate and/or confirm possible spin-lattice relaxation mechanisms. Rorschach and Hazlewood¹⁸ developed a model

for water molecules in contact with a macromolecule (or biopolymer) that are relaxed by segmental motions of the polymer and, in turn, cross relax to the solvent water molecules. This model, valid at high Larmor frequencies, predicts that

$$1/T_1 = A + B\omega_L^{-1/2} \quad (4)$$

where ω_L is the Larmor frequency and A and B are constants. This frequency dependence has been observed^{19,20} in whole excised rat lung over the range 6.7–80.5 MHz. The theory has recently been extended^{19,20} to very low Larmor frequencies and to rotating frame relaxation times ($T_{1\rho}$), and has shown excellent agreement with the results of measurements in rat lung.

3.2.2 Inflation Dependence of T_1 in Lung

Measurements of the Larmor frequency dependence of $1/T_1$ for various intact excised rat lungs, degassed as well as inflated with various gases²¹ (air, O_2 , and N_2), all agree with equation (4), but with different values for A and B . Furthermore, at any given frequency, measurements of $1/T_1$ versus inflation pressure show a linear dependence, the slope of which increases with oxygen content. Together, these results indicate that paramagnetic oxygen also plays a significant role in spin-lattice relaxation in inflated lung.²¹

4 IMAGING TECHNIQUES FOR LUNG

This section deals only with those techniques used in lung imaging. For a more general treatment of imaging techniques, see *Hyperpolarized Gas Imaging; Image Formation Methods; Spin Warp Data Acquisition; Echo-Planar Imaging, and Projection-Reconstruction in MRI*.

4.1 Asymmetric Imaging

Over the last 10 years, techniques have been developed for imaging tissues that exhibit internal inhomogeneous broadening. These techniques involve pulse sequences that are temporally symmetric or asymmetric with respect to the time interval τ between the 90° and 180° pulses and the time interval τ' between the 180° pulse and the echo (see Figure 7). With these techniques the regions in an image that are inhomogeneously broadened can easily be separated from those that are not.

Typically, a frequency-encoding magnetic field gradient G_x is applied between the 90° and 180° pulses and a rephasing gradient follows the 180° pulse. For an internally broadened sample, there will be two sources of dephasing: (1) the dephasing due to the sample-induced inhomogeneous broadening which will refocus at 2τ ; and (2) the dephasing owing to the external field gradient G_x , which will refocus at a time $(\tau + \tau')$ when the area under the gradient following the 180° pulse equals the area under the gradient that precedes it. The combined effect of these two sources of dephasing determines the amplitude of the spin echo. In a symmetric sequence ($\tau = \tau'$), these two dephasings will refocus at the same time (2τ), resulting in maximum echo height. In the asymmetric sequence ($\tau \neq \tau'$), the refocusing of the dephasing due to internal field gradients will still occur at 2τ but will no longer be coincident with the refocusing of the dephasing due to the external field

Figure 7 Pulse sequences used in NMR imaging of lung: (a) symmetric ($\tau = \tau'$); (b) asymmetric ($\tau \neq \tau'$). (Reproduced by permission of Pergamon Press from D. C. Ailion, *Magn. Reson. Imaging*, 1992, **10**, 799)

gradient G_x , which will occur at $\tau + \tau'$. Since these signals refocus at different times, the echo height obtained with the asymmetric sequence will be reduced compared with that obtained with the symmetric sequence. For normal tissue, such as liver, which shows no internal inhomogeneous broadening, the signals obtained with the symmetric and the asymmetric sequences will be equal. In contrast, the asymmetric signal in inflated lung, which shows considerable internal inhomogeneous broadening due to the air–water interfaces, will be considerably reduced compared with the symmetric signal. Thus, by subtracting voxel by voxel the asymmetric from the symmetric image, a difference image representing only those regions exhibiting internal inhomogeneous broadening can be formed.⁵

4.2 Techniques for Minimizing Motional Artifacts in Lung

A problem in in vivo lung MRI is that lung is a relatively low water density organ, adjacent to higher density regions, the heart and the chest wall, that move asynchronously due to the heartbeat and respiration, respectively. These motions cause nonlocal artifacts in two-dimensional Fourier transform (FT) images² (see *Motion Artifacts: Mechanism and Control*). Since each phase-encoded echo used to construct the image arises from the entire object, any motion of the object between successive spin echoes in the same scan will result in a widespread motional artifact. Since this artifact can result in the occurrence of wispy white regions throughout the lung, it would be difficult to distinguish these from regions of local edema. Even though these artifacts may be tolerated in some qualitative applications, they are clearly unacceptable in quantitative studies.

4.2.1 Line Scan Techniques

4.2.1.1 Conventional line scan. The nonlocal artifacts described above can be largely avoided by the use of the line scan technique,²² in which a planar region is selectively excited (see *Selective Excitation in MRI and MR Spectroscopy*) with a 90° pulse after which a perpendicular plane is excited by a 180° pulse, so that only nuclei on the line of intersection of the two planes contribute to the echo. By applying a readout gradient along this selective line, an almost instantaneous one-dimensional image of the nuclei along this line is obtained. By shifting the rf frequency slightly and repeating this process, an adjacent line can be excited. In this way a two-dimensional image can be formed from a sequence of one-dimensional lines. A major advantage of this technique is that motions will result in localized, rather than widespread, artifacts involving only the particular selective lines that include the moving nuclei. A major disadvantage of this technique compared with the two-dimensional FT and other techniques is its slowness, since a time of the order of T_1 must elapse between each successive line scan. A second disadvantage is that the spatial resolution is usually poorer than with two-dimensional FT, because of the difficulty in selectively exciting spatially adjacent regions without overlap. The signal-to-noise (S/N) ratio is considerably poorer than with two-dimensional FT, in which data are obtained from an entire plane rather than from a single line. The first disadvantage (slowness) can be circumvented by the use of the rapid line scan (RLS) (see below). The second disadvantage (poor spatial resolution) can be reduced by interleaving the excitation order, using the interleaved line scan (ILS) technique (see below).

4.2.1.2 Rapid line scan. The slowness of the conventional line scan, due to the need to wait a time of order T_1 between successive scans, can be overcome by selectively exciting lines along a diagonal plane, rather than along either the 90° or 180° planes. In this case, the NMR signals from each line come from previously unexcited nuclei, so that successive lines can be excited in rapid succession, without requiring a delay of the order of T_1 . The implementation of this sequence is similar to that of conventional line scan, except that the rf frequencies of both the 90° and 180° pulses are shifted before the next line scan.

One potential problem with this simple scheme is that spurious echoes can arise from the nuclei from previously excited planes. However, by simply applying spoiler gradients after each echo, the spurious echoes can be eliminated.²

Using the above technique an entire planar image can be excited within a single T_1 . This RLS technique gives a S/N ratio similar to that of two-dimensional FT, but without the motional artifacts. Furthermore, it can produce a fully resolved planar image in the time required for the simple two-dimensional FT technique to obtain only one phase encode.

4.2.1.3 Interleaved line scan. A disadvantage of the RLS technique is that its spatial resolution in lung studies is usually much poorer than that of other techniques. Because of the relatively short T_2 of lung tissue, long highly selective rf pulses cannot be used. Because of the resulting imperfect slice selection, spins near the boundaries of the 90° and 180° planes are only partially excited, resulting in signal loss when the successive lines are closely spaced. This signal loss can be minimized by spacing the lines sufficiently far apart, resulting in limited spatial resolution. The signal loss can be reduced

and/or the spatial resolution improved by waiting a time of the order of T_1 between successive line scans. By interleaving the excitation order, adjacent line scans are separated temporally but without losing information from regions between the lines. Thus the ILS is a compromise between the higher speed RLS and the higher resolution conventional line scan technique. In imaging longer T_2 systems, more highly selective rf pulses can be used, so that improved resolution can be obtained with RLS in a relatively short time.

4.2.2 Rapid Projection–Reconstruction (PR) Technique

Another technique²³ which produces motional artifact-free images consists of using a slice-selection self-refocusing rf pulse followed immediately by two orthogonal frequency encoding gradients (see *Projection–Reconstruction in MRI*). By using a self-refocusing pulse, the time needed for the refocusing gradient lobe is eliminated, so that a FID can be obtained immediately after the rf pulse. By varying the relative strengths of the orthogonal gradients, different projections can be obtained. Since the NMR signal is acquired immediately after the slice-selective excitation, essentially all biological motional artifacts are eliminated. Another feature of PR imaging is that the low-frequency data are oversampled, which is analogous to averaging the gross features of the object being imaged. Motional artifacts appear as streaks, largely outside the region of interest. This technique can obviously be applied to short T_2 systems, and has been successfully used in lung imaging.²⁴ Even though this technique clearly gets rid of the ghost-like artifacts of the two-dimensional FT techniques, it is not entirely free from motional errors. The time between the rf pulse and the data acquisition can be very short, but the time between successive projections would be of the order of T_1 , with the result that motions within this time interval can result in noisy or distorted images. It is not necessary to wait a time of the order of T_1 between successive projections if small flip angles are used; however, the S/N ratio will be reduced considerably with this procedure. Another disadvantage of this technique is that the projection–reconstruction procedure requires a relatively long time to form a complete two-dimensional picture, since many projections are required. Nevertheless, under favorable conditions projection–reconstruction techniques have been able to obtain finely detailed microscopic pictures of rat lung.

4.3 Gas Imaging

A desirable complement to the tissue imaging described earlier in this article would be to image inhaled gases directly in the airways and alveoli. It is essentially impossible to image the air directly because of the very low density of paramagnetic nuclei and the corresponding small signal. However, two different approaches have been introduced in recent years that allow the direct imaging of the inhaled gases. One uses inhaled fluorinated gases in which the ^{19}F is imaged directly and the other uses inhaled hyperpolarized inert gases (either ^3He or ^{129}Xe) (see *Hyperpolarized Gas Imaging*). The advantages of gas imaging using nuclei other than protons are (1) significant reduction in susceptibility distortion (because the alveoli are, to a first approximation, spherical), (2) elimination of artifacts arising from the motions of nearby high-density tissue (heart, chest wall), since these tissues will not contain

the nuclei being imaged (i.e., the inhaled fluorocarbons or hyperpolarized ^3He); (3) enhanced signal-to-noise, particularly for the hyperpolarized gases, and (4) the ability to observe directly the gas exchanging regions (alveoli, bronchi) whose properties can be inferred only indirectly from proton tissue imaging.

4.3.1 Fluorinated Gas Imaging

These imaging techniques typically involve inhaling fluorinated gases (e.g., hexafluoroethane or sulfur hexafluoride) mixed with approximately 20% oxygen. Because of the short ^{19}F T_1 (about 5.9 ms in hexafluoroethane),²⁵ the relatively low density of the ^{19}F in the gas can be partially compensated for by the higher efficiency of the signal averaging. Nevertheless, the signal is still somewhat reduced, and considerable time is required to obtain good images. In spite of this drawback, impressive images of the lungs of live rats²⁵ have been obtained in about 4 h. This technique has recently been applied to the detection of obstructed ventilation in the airways of lung, which results in an increased fluorocarbon concentration.^{26,27} The main advantages of this technique over the use of hyperpolarized gases, to be described below, are its lower cost and experimental simplicity as well as its reduced sensitivity to oxygen relaxation. Its main disadvantage is that it is limited to imaging steady-state gas concentrations because of its lower sensitivity and the corresponding longer time required to obtain an image.

4.3.2 Hyperpolarized Gas (^3He or ^{129}Xe) Imaging

Hyperpolarized gas imaging is also called spin exchange²⁸ and is based on using laser light to prepolarize alkali nuclei (typically Rb) via the electrons and then to transfer this polarization to the nuclei that are to be imaged (^3He or ^{129}Xe). A variant of this technique (called metastability-exchange optical pumping)²⁹ involves direct optical pumping of the ^3He and does not involve Rb metal. The pumping efficiencies are comparable to those of spin exchange, but the metastability technique can be used only for ^3He and not for ^{129}Xe . These techniques can increase the signal strength of the polarized nucleus by four or five orders of magnitude, resulting in a signal strength that is even an order of magnitude larger than that of protons in a comparable volume of tissue.³⁰ Because of this enormous signal strength, signal averaging is not really necessary and images can be obtained within a signal breathing cycle. Comparing the advantages and disadvantages of ^3He and ^{129}Xe , the ^3He spin polarization has a much longer lifetime than that of ^{129}Xe . Furthermore, ^3He does not penetrate tissue, in contrast to ^{129}Xe , which readily dissolves in blood and tissue. As a result, ^3He is probably preferable for imaging the voids in the lung, whereas ^{129}Xe may be more useful for imaging tissue or gas–tissue mixtures (as in the alveolar regions of the lung). Both nuclei have been used to obtain high-quality images in humans.^{31,32} Recently, ^3He has been reported to have been able to detect emphysema in humans.³³ The emphysema causes decreased elasticity in the alveolar walls, resulting in a decreased ability of the alveoli to expand upon inhalation. This results in a lower gas concentration in the emphysematic regions, resulting in a reduced signal intensity compared with that of the normal regions. Also, regional differences in apparent D values of the ^3He owing to the breakdown of alveolar

walls have been observed in emphysemic patients.³⁴ These patients also exhibit abnormal ventilation patterns in rapid 'real-time' echo-planar lung imaging.

Magnetization Transfer between Water and Macromolecules in Proton MRI

Robert S. Balaban

National Heart, Lung and Blood Institute, Bethesda, MD, USA

1 INTRODUCTION

Biological macromolecules enhance water spin-lattice relaxation.¹⁻⁵ The potential mechanisms for this phenomenon have been appreciated since the early 1970s and are presented in Figure 1 which was adapted from Noack.⁶

These early theoretical evaluations established that several kinetic and geometric factors are important in determining the extent of the relaxation enhancement. These include the correlation time of the water proton/macromolecular complex (i.e. as restricted water or proton chemical exchange sites), chemical and diffusion exchange rates, as well as the proximity of the water and macromolecular protons. More recent studies have suggested that the through-space dipolar coupling pathway between the restricted motion protons of the macromolecules and a small pool of water protons is the major relaxation pathway.^{1,7-9} This interaction apparently involves a small portion of the hydration water protons with a net correlation time in excess of 10^{-8} s, caused by either the titration of a proton-accepting site or the restriction of water itself. This dipolar coupling between the macromolecule protons and water results in a magnetization transfer pathway between these spin baths

which results in the coupled cross relaxation between water and macromolecule protons.

The most notable approaches in the past to studying macromolecule/water interactions have used selective inversion transfer^{5,10} and field dependence techniques¹¹ which have established many of the limiting parameters for these interactions in tissues and model macromolecule systems. Several mathematical approximations for this process have been presented in the literature,^{1,12-14} however, the actual nature of the water and macromolecule proton magnetization transfer pathway is still not understood with regard to the chemical nature of the interaction sites and the specific rate-limiting steps.

Interest in this topic was increased recently by the demonstration that saturation transfer between macromolecule and water protons can be used to assay the extent of magnetization transfer in vitro and in vivo.¹⁵ This simple approach combined with conventional MRI techniques also permitted the determination of the topology of this interaction in biological tissues.¹⁵

The use of saturation transfer techniques in monitoring the water/macromolecule magnetization transfer process is dependent on the relaxation differences between water and macromolecule protons resulting in distinctly different NMR lineshapes. A schematic diagram outlining the use of saturation transfer to monitor magnetization transfer is presented in Figure 2.

The restricted motion of the macromolecule protons results in a very short spin-spin relaxation rate (T_2) with an intermediate T_1 . This results in a very broad NMR lineshape extending many kHz off-resonance. In contrast, the water protons have a very short correlation time, $\sim 10^{-11}$ s, resulting in relatively long relaxation times and narrow linewidths on the order of 10–20 Hz, in vivo. Thus, by applying an irradiation energy sufficiently off-resonance as shown in Figure 2, the molecular protons can be preferentially saturated. Any chemical exchange or magnetization transfer between the water and macromolecular protons will result in a decrease in the water proton signal or saturation transfer as originally described by Forsén and Hoffman for simple chemical and dipolar interactions.¹⁶ Using

Figure 1 Schematic diagram of water/macromolecule magnetic interactions highlighting the pathways and relevant pools. Adapted from Noack⁶

Figure 2 Schematic diagram of water and macromolecule proton linewidths (top), and the use of an off-resonance irradiation to detect magnetization transfer in tissue where both lines overlap (bottom)

this scheme, tissues with strong macromolecule/water proton magnetization exchange will have a lower water proton NMR signal in the presence of the off-resonance irradiation.

The contrast generated in these images has been termed magnetization transfer contrast (MTC). Using this approach, Wolff and Balaban¹⁵ showed that the magnetization transfer pathway between water and macromolecules could be detected in biological tissues *in vivo* using an off-resonance irradiation scheme, and that the topology of the interaction could be determined by combining MRI techniques with the off-resonance irradiation. This is accomplished by simply applying the off-resonance irradiation in an appropriate power and duty cycle anytime when the gradients will not interfere with the frequency selectivity or the irradiation will interfere with the data acquisition.^{15,17}

2 CONTROLLING PARAMETERS IN SATURATION TRANSFER

There are several key parameters in the off-resonance saturation transfer technique which can alter the quantitative and qualitative aspects of the experiment as well as provide unique information on the macromolecule dynamics. The effect of the irradiation will have a frequency, power, and time or duty cycle dependence.¹⁷ All of these parameters can affect the magnitude of the negative NOE observed with off-resonance irradiation, as well as the source of this phenomenon which might not involve magnetization transfer alone as will be discussed below.

2.1 Frequency/Power of Irradiation, The Magnetization Transfer Spectrum

The frequency dependence of the interaction is intimately linked to the power applied.^{17,18} An example of the frequency dependence of the water proton signal as a function of off-resonance frequency at fixed power is presented in Figure 3 for sphingomyelin at two different temperatures, *in vitro*. Also presented are the calculated effects of the irradiation on water alone based on its measured T_1 and T_2 relaxation times. The large difference between the predicted and observed effect of the off-resonance irradiation is due to the magnetization transfer effect resulting in a decrease in water proton signal with irradiation far off-resonance.

These spectra have been called magnetization transfer spectra (MT spectra) or Z spectra.⁹ At 25°C, below the phase transition temperature for sphingomyelin, the MT spectrum is ~30 kHz with a distinctive Gaussian characteristic consistent with the rigid lipid structure below its phase transition. At 65°C, above the phase transition, the linewidth collapses to <10 kHz with a more Lorentzian lineshape consistent with the increase in lipid mobility above the phase transition. From the characteristics of the MT spectrum, the spectral density and associated dynamics of the macromolecules involved in the interaction can be determined as demonstrated in this simple lipid model.

The changes in the macromolecule MT spectrum with temperature illustrate the importance of calibrating the off-resonance irradiation scheme used for the macromolecular sys-

Figure 3 Effect of off-resonance irradiation frequency on sphingomyelin bilayer water signal. Experiments were conducted at 4.7 T with a 50/50 wt.% sphingomyelin preparation. Irradiation power was 1×10^{-6} T. The amplitude of the water signal is normalized to 100. Data for 25°C (below the lipid phase transition) and 65°C (above the phase transition) are presented. The solid line is the calculated effect of the off-resonance irradiation based on the measured relaxation times of the water protons¹⁷

tem. Models of even simple macromolecular systems demonstrate that predicting the optimal irradiation frequency/power is extremely difficult due to the complex nature of the macromolecular structure and the interaction. Indeed, it is clear that the MT spectrum represents a complex sum of all of the coupled spins in the macromolecule. This was recently demonstrated using site-specific deuterium labeling in lipid systems¹⁹ which reveals the different motional domains interacting with water in this simple system, resulting in the net spectrum presented in Figure 3. These results demonstrated that the magnetization transfer spectrum will only reflect the average motions of all of the coupled spins within the macromolecule and not the interaction site alone. This may have major consequences in the use of magnetization transfer spectra for *in vivo* tissue characterization.

An example of an off-resonance irradiation frequency study on the human brain is presented in Figure 4 where a fixed power is applied at different off-resonance frequencies. The marked change in tissue contrast is clearly observed and the magnetization transfer spectrum of each tissue type can be extracted. An optimum in gray matter/cerebrospinal fluid contrast was obtained at ~1000 Hz off-resonance with 6 W continuous wave in this 4 T study as shown in Figure 5. It is also important to note that the magnetization transfer effect could even be optimized at 4 T below the SAR guidelines of the US Food and Drugs Administration. Thus, MTC can be generated well below the rf levels of concern at lower fields.

Though magnetization transfer contrast has proven to be extremely useful in numerous MRI examinations as discussed below, little attention has been applied to the use of the MT spectrum *in vivo*. Due to the complex nature of the MT spectrum, the only way to assure that a specific and optimal MT effect is being observed is to perform an MT spectrum study on the tissues of interest.¹⁷ Numerous values are now available in the head for accepted parameters (references follow in appli-

Figure 4 Effect of off-resonance irradiation frequency on MTC of the human head at 4T. Data were collected with varying off-resonance irradiation frequency in gradient recalled echo images ($TE = 6.5$ ms, $TR = 500$ ms). The irradiation was 6 W applied CW for 450 ms just before the slice selection. A gradient spoiling pulse was applied immediately after the irradiation to cancel any remaining transverse magnetization induced by the off-resonance irradiation. The off-resonance irradiation frequency was stepped-up 200 Hz/image from on-resonance in the first 10 images reading right to left from the top. The last images are at 3000, 4000, 5000, and 7500 Hz off-resonance

cations section); however, other tissues will require more studies to develop the most appropriate irradiation frequency and power for a given contrast requirement. This is not unlike what has already been done to determine the optimal TE , TR and flip angle values to detect pathology using conventional MRI.

2.2 Macromolecule Irradiation Schemes

There have been numerous methods published in the literature to apply off-resonance irradiation in an MRI study. These methods include continuous wave (CW) irradiation which is highly accurate and effective only when adequate time is available during the TR period,^{15,17} or shaped pulses which provide a method of presenting a well-defined frequency irradiation in a short period of time, much the same way as fat suppression or slice selection is performed in conventional MRI.^{20–22} Another method involves the use of an on-resonance jump and return method²³ which is very power

efficient but critically dependent on B_0 homogeneity. Yeung and Aisen²⁴ have provided a good theoretical analysis of the pulsed methods along with several studies comparing CW and pulse methods²⁵ as well as duty cycle and power issues.^{21,26,27} In summary, due to the homogeneity limitations of the on-resonance jump and return methods, shaped frequency-defined off-resonance pulses seem to be the most appropriate time efficient excitation method for MRI studies. Naturally, any approach will still require the frequency/power calibration discussed above.

2.3 Nonmagnetization Transfer Effects of Off-Resonance Irradiation

It is also important to note that the effects of off-resonance irradiation is not limited to the magnetization exchange processes discussed above. Due to the nature of the Lorentzian line of water, the off-resonance irradiation if not properly con-

Figure 5 Contrast data from the images presented in Figure 4. The gray matter/cerebrospinal fluid (CSF) contrast (i.e. difference) is plotted as a function of irradiation frequency. An optimal contrast is obtained at ~1000 Hz off-resonance

trolled can also result in several interesting direct effects on the water line which are not directly related to macromolecule/water magnetization transfer. The most notable of these are the direct saturation effects¹⁷ which will reduce net water magnetization based on its T_1 and T_2 ²⁸ or T_1 values in the rotating frame.²⁹ Both these effects occur if the irradiation power is sufficiently high to affect the water protons directly, independently from the magnetization transfer interaction with the macromolecules. In a properly calibrated magnetization transfer experiment these effects should be minimized, but will always influence the MT spectrum at high power or close to on-resonance conditions.^{17,30} An excellent comparison of magnetization transfer and the spin locking phenomenon has been provided recently by Kuwata et al.³⁰

2.4 Time-Dependence

The time-dependence of the irradiation is rather more straightforward. Since the rate of magnetization transfer is on the order of 1 s^{-1} , it takes seconds for the two spin populations to reach steady-state magnetization levels.^{15,18} This has very important consequences with regard to the quantitation of magnetization transfer rates, as well as the optimization of magnetization transfer contrast. For quantitative studies, either the time-dependence has to be determined or long preirradiation times must be used to assure steady state. In imaging experiments, the duty cycle of the irradiation must be adequate to maintain the macromolecular saturation in conventional phase-encoding schemes or the magnetization preparation period must be on the order of seconds in fast imaging techniques.³¹

3 QUANTIFICATION

As far as the absolute quantification of the magnetization transfer rate is concerned, the powerful simplification provided

by the Forsén–Hoffman approach requires that complete saturation of the macromolecular pool be obtained. This condition has been apparently reached in some *in vivo* systems^{15,18} but clearly not in some *in vitro* model systems.¹³ Indeed, due to the rapid magnetization exchange between the macromolecular system and the very large water proton pool, reaching saturation by irradiating the macromolecules alone may prove difficult in many systems. Without this key simplification, the quantification of the magnetization transfer rate becomes dependent on complex models with numerous unknowns¹³ even if the aforementioned compartmentation of the macromolecules is not taken into account. These data suggest that the absolute quantification of magnetization transfer rates *in vivo* may be extremely difficult if the Forsén–Hoffman approximation cannot be used. However, to date it is not clear whether the actual magnetization transfer rate, MTC, or MT spectrum will be the most useful in evaluating pathology. In any event, the proper quantification of the effect will greatly aid our understanding of the molecular mechanisms involved in the process.

4 APPLICATIONS

Magnetization transfer contrast is most useful in two basic areas: improving image contrast and tissue characterization. It can generate contrast with minimal TE values, reducing motion, susceptibility, and flow artifacts.¹⁷ Improvements in image contrast have been reported in the musculoskeletal system,^{27,32} brain,^{33–35} liver,^{36–38} eye,³⁹ and heart.^{40–43} MTC has also proven to be extremely useful in the reduction of the ‘background’ signal in MRA and contrast agent studies. Since there is very little water/macromolecule magnetization transfer in blood, and the macromolecules that are there are difficult to saturate due to flow, the blood signal is only slightly decreased in MTC while the surrounding tissue is decreased. This additional background suppression by MTC results in the resolution of smaller vessels in MRA.^{44,45} Since contrast agents are usually trapped in regions with low macromolecule/water magnetization transfer, the signal enhancement by T_1 contrast agents usually complements the MTC effect. This additive effect has been shown to reduce the dose requirements in MR contrast agent studies.^{46–48}

Much less work has been done with regard to tissue characterization with magnetization transfer. Studies have revealed that the effect is very specific to particular macromolecules in rather complex tissues. Collagen seems to be the most effective macromolecule in cartilage⁴⁹ and meningiomas,⁵⁰ while surface –OH groups seem to be critical in lipid systems.^{7,51,52} Studies on a large number of macromolecules reveal that surface –OH groups may be the most effective site in most macromolecules,⁷ but whether this is due to the titration of the site or coordination of water⁵³ is yet to be definitively demonstrated. The importance of water content has also been demonstrated in the heart.⁴⁰ More complete studies and hypotheses must be generated to evaluate whether the magnetization transfer effect can be used to improve the specificity of MRI examination. Potentially the use of the magnetization transfer spectrum will aid in this effort.

5 SUMMARY

In summary, the use of water/magnetization transfer has proven to be a useful tool in the evaluation of water/macromolecule interactions as well as providing another contrast tool in MRI examinations. As our understanding of the molecular processes involved in this interaction improves, the specificity and utility of MTC in clinical MRI will also benefit.

Magnetization Transfer Contrast: Clinical Applications

Christine J. Baudouin

Freeman Hospital, Newcastle upon Tyne, UK

1 INTRODUCTION

The signal obtained in clinical magnetic resonance imaging comes from mobile protons. These are largely present in free water with a smaller contribution from lipid. There are, in addition, a large number of protons in tissues contained in macromolecules or in water bound to these macromolecules. No signal is normally detected from these protons by standard clinical imaging techniques because they have a very short T_2 value (of the order of 1 ms or less) and any transverse magnetization is rapidly dephased before data collection is possible.

There is, however, a constant exchange of magnetization between the protons in these two pools, the free pool and the bound pool, which occurs by through-space dipole–dipole interactions or probably less importantly direct chemical exchange. By means of this interchange, the bound pool influences the signal obtained from the free pool even though the bound pool cannot be directly visualized.

In magnetization transfer (MT) imaging, the normal equilibrium between free and bound pools is perturbed and the resulting contrast, magnetization transfer contrast, is an indication of the exchange processes with the bound pool in that particular tissue. Greater detail on the theory and tissue interactions involved will be found in the related articles on magnetization transfer. The techniques described in this article are those concerned with clinical imaging.

2 MAGNETIZATION TRANSFER TECHNIQUES IN CLINICAL IMAGING

Magnetization transfer or saturation transfer techniques have been used in magnetic resonance spectroscopy for many years.^{1,2} Despite an early report of the use of off-resonance saturating irradiation in 3D imaging of the limbs in 1983,³ interest in possible clinical applications was not stimulated until Wolff and Balaban published their initial findings in 1989.⁴ These authors perturbed the normal equilibrium between free and bound pools by selectively saturating the bound pool. The signal obtained from the free pool decreased, and the degree of signal reduction varied between tissues. Adipose tissue showed little reduction in signal; kidney and muscle showed greater magnetization transfer effects.

2.1 The Saturating Pulse

The bound pool has a broad linewidth reflecting its short T_2 , while protons in the free pool have a narrow linewidth reflecting their longer T_2 values. A saturating pulse placed off-resonance can saturate the bound pool while having minimal direct effect on the free pool. Any reduction in signal in the free pool caused by the saturating pulse then represents magnetization transfer effects. A similar effect can be obtained by using a composite pulse, such as a binomial pulse.⁵ The latter approach gives lower radiofrequency absorption rates (SARs) than off-resonance irradiation but is more technically demanding.

As the duration or amplitude of an off-resonance pulse of a given frequency is increased, the signal obtained from a tissue which shows magnetization transfer effects, such as muscle, decreases to a plateau.^{6,7} As the frequency offset of the saturating pulse is reduced towards zero, signal from tissue falls due to magnetization transfer effects until at small offsets direct saturation of the free pool occurs. Ideally the saturating pulse should give maximal saturation of the bound pool with no direct saturation of the free pool, but often a compromise is necessary in clinical imaging.

The saturating pulse is thus characterized by offset frequency, duration, and amplitude. In addition, it may be applied continuously or as pulses of various configurations. All of these characteristics alter the degree of saturation obtained and must be known before quantitative comparisons can be made between different clinical studies.

2.2 Effect of Saturating Pulses on Normal Tissue

Tissues which demonstrate magnetization transfer show two changes in the presence of saturating pulses:

1. A reduction in available longitudinal magnetization.
2. A reduction in T_1 , the new value being termed $T_{1\text{sat}}$.

It is possible to measure both of these values and calculate the rate constant for magnetization transfer (k_t). Values are available for animal tissue,^{4,8,9} normal human muscle, and gray and white matter.^{6,7}

It is time-consuming to obtain the measurements necessary to derive these values and few figures are available for human pathological tissue in vivo.¹⁰ Instead a simple measurement of the reduction in signal intensity of a tissue when a saturating pulse is applied is usually quoted in clinical studies.

Confusingly, this may be given either in the form M_s/M_0 or $1 - M_s/M_0$ where M_s is the signal intensity of a region of interest (ROI) on a scan obtained in the presence of a saturating pulse and M_0 is the signal of the same ROI on a scan obtained with no saturating pulse. Such values allow comparison of magnetization transfer effects in different normal and abnormal tissues within one MR unit but are highly dependent on the base sequence used, characteristics of the saturating pulse, and field strength and, therefore, the results from different institutions cannot be readily compared. Numerical values may be given, or the information displayed as a difference image. When numerical values are given in this article the notation M_s/M_0 will be used.

Simple fluids, e.g. cerebrospinal fluid (CSF), bile, and urine, show little magnetization transfer, presumably due to the small

number of macromolecules present. Fat also shows little change in signal as the protons in fat do not exchange with the bound pool.⁴ Skeletal muscle shows the largest magnetization transfer effect with a reduction in signal to approximately one-third of the normal value (M_s/M_0 of the order of 0.3),^{6,7} with articular cartilage also showing a large effect.¹¹ Spleen, liver,^{12,13} kidney,⁴ and brain tissue^{6,14} show intermediate effects. Within organs, different components show different degrees of MT, e.g. renal cortex more than medulla,^{4,8} and white matter more than gray matter.^{6,14}

Stationary blood has a relatively small MT effect^{4,12} and flowing blood is not subjected to the same degree of saturation as stationary tissues. Both of these features contribute to the improvement of time-of-flight angiography in the presence of MT pulses.

2.3 The Use of Saturating Pulses with Imaging Sequences

Initial magnetization transfer studies *in vivo* generally combined a saturating pulse with a spin echo or gradient echo sequence of long repetition time (TR) and short echo time (TE), or shorter TR and a low flip angle.^{12–15} Such sequences have little T_1 or T_2 weighting and are of low intrinsic contrast; the addition of an off-resonance pulse increases contrast between tissues showing magnetization transfer effects (e.g. muscle) and those that do not (e.g. adipose tissue). This is the approach usually employed when a quantitative measure of magnetization transfer is required.^{12–14} In this instance, the reduction in signal observed is largely due to the reduction in available magnetization, the alteration in T_1 under saturating conditions playing little or no part. As already mentioned, quantitation allows comparison of results only when all imaging parameters are kept constant.

An alternative strategy to quantitation in clinical magnetization transfer imaging is to use the technique to develop clinically useful contrast and improve lesion conspicuity. It may then be useful to use sequences which exploit T_1 alterations in addition to the reduction in available magnetization such as short TR , short TE T_1 -weighted spin echo sequences, and inversion–recovery sequences.⁶ Saturating pulses can (and often have) been applied to virtually any imaging sequence including volume imaging^{3,11} and ultrafast sequences where the saturating pulse can be used as the preparation pulse for single shot techniques.¹⁶

2.4 Safety Issues in Clinical Imaging

Initial magnetization transfer experiments required hardware modifications to provide the necessary saturating pulses and resulted in the deposition in tissues of relatively large amounts of power. The problem of power deposition is most worrying at high field strength and much of the early human work was performed at low field strength (0.1 or 0.15 T). A number of methods for overcoming these problems have been developed.

1. Balaban and Ceckler¹⁷ showed that the power of an off-resonance saturating pulse can be reduced and the same degree of signal reduction maintained if the frequency offset is also

reduced. As offset frequency is reduced, care must be taken to avoid direct saturation effects.

2. The use of pulsed radiofrequency which may be off-resonance or binomial.⁵ Binomial pulses result in lower SARs but appear to be technically more demanding in clinical imaging.
3. Off-resonance radiofrequency can be used as the preparation pulse for a fast imaging sequence.¹⁶

Using these modifications, MT can now be routinely implemented on clinical imaging systems (i.e. up to 1.5 T) without major hardware modifications and with power absorption within present guidelines.

3 CENTRAL NERVOUS SYSTEM

CSF shows little magnetization transfer, while normal brain tissue shows moderate signal loss.^{6,14} Normal white matter has a slightly greater reduction in signal than normal gray matter. There are also regional variations in the exact degree of MT effect within gray and white matter, with occipital white matter showing less magnetization transfer than other white matter regions.¹⁸

Although the signal from CSF does not alter with the application of saturating pulses, it may become of higher signal intensity than normal brain. Rescaling of the images results in CSF appearing bright, as illustrated in Figure 1.

3.1 Multiple Sclerosis

The most thorough investigation of magnetization transfer in a single disease process has been made in multiple sclerosis. Dousset et al.¹⁴ using a 3D gradient echo sequence studied 15 patients, and reported a wide variation in the reduction of signal, from 2–36% reduction ($M_s/M_0 = 0.98–0.64$) in individual plaques with a mean of 26.3% ($M_s/M_0 = 0.73$) compared with a 40% reduction ($M_s/M_0 = 0.60$) from normal white matter in volunteers. The authors suggest this variation between lesions may represent differences between acute plaques with edema and inflammatory response and chronic plaques with more marked demyelination and gliosis (which may show smaller magnetization transfer effects). Such differentiation of the age of plaques would be useful not only for diagnosis but for implementing and monitoring the effects of appropriate treatment. This group also found a decrease in magnetization transfer in the normal appearing white matter of their patients, particularly those with chronic and/or progressive multiple sclerosis compared with normal volunteers which could be important in determining prognosis in individual cases.

Gass et al.¹⁸ also found a variation in the degree of magnetization transfer in plaques of demyelination and found that this correlated with the severity of disability, the lesions in patients with more severe disability showing less magnetization transfer, i.e. a higher M_s/M_0 value.

Further work has confirmed and expanded these findings.^{19–21}

Magnetization transfer techniques may reflect histological changes in multiple sclerosis and help to predict long-term outcome.

Figure 1 Mildly T_2 -weighted spin echo scan ($TR = 2500$ ms, $TE = 20$ ms) (a) without and (b) with off-resonance irradiation of a patient with an astrocytoma. The signal from normal gray and white matter is markedly reduced in (b), while there is no change in the signal from CSF. Rescaling of the image results in CSF appearing bright. The cystic component of the tumor (large arrow) shows little magnetization transfer while the solid component (arrowheads) and edema (small arrows) show intermediate loss of signal

3.2 Cerebral Infarcts

In general, as in multiple sclerosis, pathological tissue shows less magnetization transfer than the corresponding normal tissue. Such an effect has been seen in infarcts both in rats²² and humans.^{6,23} Magnetization transfer measurements may help to distinguish demyelinating plaques from ischemic lesions.²⁴

3.3 Neoplasms

There have been a number of reports of quantitative magnetization transfer in various brain tumors.^{10,23,25,26} These results and our own work show a very variable degree of magnetization transfer between different tumors and between different components of the same tumor in one patient. Overall pathological tissues show less magnetization transfer than normal white matter, although isolated cases of meningioma, pituitary adenoma, acoustic neuroma, and one metastasis show similar levels. In the largest study, Kurki et al.²⁶ studied 28 patients with intracranial tumors at 0.1 T using a T_1 -weighted gradient echo sequence ($TR = 200$ ms, $TE = 20$ ms). The mean M_s/M_0 value for the tumors was 0.77, compared with a mean value in normal appearing white matter in the patients of 0.69. Astrocytomas tended to show less magnetization transfer than hemangioblastomas, meningiomas, and pituitary adenomas.

Within a single lesion, cystic components show little or no magnetization transfer, with different solid components showing greater signal loss, as illustrated in Figure 1. We have found cystic components to have an M_s/M_0 value of 0.84–0.98, while the range in solid components in one patient was as great as 0.61–0.84. Small magnetization transfer effects are often

seen in hemorrhage²³ while edema shows intermediate magnetization transfer. The degree of cellularity and nature of the tissue correlate to some extent with magnetization transfer²⁵ but as yet do not allow histological differentiation of tumors on imaging. The variability of measurements within individual lesions and within types of lesions is likely to limit the role of simple quantitative measurements. More exhaustive measurements, for example exchange rate constants, may be more tissue-specific.¹⁰

The discussion so far has concentrated on quantitative measurements. An alternative approach is to combine saturating pulses with other sequences, with more inherent contrast and sequences which also exploit T_1 effects such as the STIR sequence⁶ or short TR , short TE T_1 -weighted sequences. The signal from normal gray and white matter can be markedly reduced using a magnetization transfer STIR (MT-STIR) sequence leaving lesions seen with high contrast.⁶ In fact, this may be one instance in which using maximal saturation is not ideal, as the signal from normal tissues may be reduced so much that normal anatomy is obscured and overall image quality is reduced. Backing off on amplitude, duration, or offset of the saturating pulses may result in a more useful image.

Magnetization transfer short TR /short TE T_1 -weighted scans may show dramatic signal changes in both normal and pathological tissues. In Figure 2, central gray matter is of lower signal intensity than normal white matter on the standard T_1 -weighted scan, but the relative signal intensities are reversed on the scan with saturating pulses as gray matter shows less signal loss than white matter. A similar reversal of contrast is seen in edema in this image. Lesions with a short T_1 due, for example, to hemorrhage or calcification, may be highlighted using this technique.²⁷ These sequences are also used when

Figure 2 T_1 -Weighted spin echo scans ($TR = 760$ ms, $TE = 20$ ms) (a) without and (b) with off-resonance irradiation showing a vascular malformation with surrounding edema. Edema shows less magnetization transfer than normal brain tissue and is of higher signal intensity than surrounding normal gray and white matter on scan (b). Normal caudate (arrow) shows less magnetization transfer than normal white matter. Regional variation in degree of signal loss is seen within white matter with less signal loss in the occipital region

magnetization transfer is combined with the administration of exogenous contrast agents.

3.4 Contrast Agents

Many intracranial tumors are enhanced by intravenous contrast agents²⁸ such as gadolinium diethylenetriamine pentaacetic acid (DTPA) and these tumors often show less magnetization transfer than normal tissue. Combining the two techniques might therefore improve visualization of contrast enhancement. Tanttu et al.²⁹ showed this to be true in vitro and in vivo, and in a larger clinical study Kurki et al.²⁶ reported improved contrast to noise for lesions post-gadolinium in the presence of an MT pulse compared with no MT pulse in 25 out of 28 patients with intracranial tumors. On standard T_1 -weighted scans, lesions are frequently hypointense to normal white matter. Application of saturating pulses, with greater signal loss in normal tissue, may result in lesions becoming hyperintense as in Figure 2, but could also cause lesions to become isointense or less hypointense than on the standard image. MT T_1 -weighted scans pre-gadolinium may result in lesions being less well seen than on standard T_1 -weighted images. However, such scans are important to obtain in order to distinguish magnetization transfer effects from exogenous contrast enhancement on post-gadolinium MT T_1 -weighted scans.³⁰ Figure 3 demonstrates the use of magnetization transfer with gadolinium in a patient with multiple meningiomas. Phantom studies suggest that in the presence of saturating pulses, gadolinium not only reduces T_1 but also alters available magnetization giving a synergistic effect in short TR scans.³¹

Initial studies suggest that although lesion-to-background ratios may not be quite as high for standard dose gadolinium

studies combined with MT as high dose gadolinium without MT, standard dose gadolinium MT studies detect as many, if not more, lesions than triple dose gadolinium.^{32,33} Unfortunately it does not seem that half-standard gadolinium with magnetization transfer can replace standard dose imaging.³⁴

4 THE HEART

Images of the heart are degraded by severe motion artifact on T_2 -weighted sequences with long echo times. Fast T_1 -weighted scans are less motion artifacted and show good contrast between blood in the ventricular cavity and the ventricular wall, but do not demonstrate intrinsic abnormality of cardiac muscle well. Magnetization transfer techniques markedly reduce the signal from normal skeletal and cardiac muscle while blood is virtually unaffected, due to its macromolecular constitution and inflow effects. Using a surface transmit/receive coil, Balaban and colleagues³⁵ showed improved contrast between ventricular cavity and wall when MT was combined with gradient echo sequences with short TE values. Magnetization transfer may be useful for volumetric studies, and the authors also postulated that the technique may be useful for tissue characterization in abnormal myocardium.

5 THE BREAST

At present, intravenous paramagnetic contrast agents are recommended in MR mammography. Magnetization transfer reduces the signal from normal fibroglandular breast tissue

Figure 3 T_1 -Weighted spin echo scans ($TR = 580$ ms, $TE = 20$ ms) post-gadolinium (a) without and (b) with off-resonance irradiation in a patient with multiple meningiomas. Signal from normal gray and white matter is reduced in (b) compared to the two enhancing lesions

while potentiating contrast enhancement in abnormal areas. The abundant adipose tissue in the breast shows no MT effects and high signal fat may obscure subtle enhancement by gadolinium. Pierce et al.³⁶ implemented a three-dimensional fat-suppressed steady-state sequence with magnetization transfer and demonstrated good contrast enhancement in carcinomas, an adenoma, and fibrocystic change, but not in fat necrosis or postoperative scar.

Schreiber et al.³⁷ found gadolinium enhancement combined with magnetization transfer useful in detecting enhancing breast lesions.

6 THE ABDOMEN

Two reports of magnetization transfer imaging of hepatic lesions at very different field strengths have shown variable results. Kahn et al.¹³ working at 0.1 T studied 18 patients with primary or secondary neoplasms using a single-slice gradient echo sequence ($TR = 1000$ ms, $TE = 30$ ms) with saturating pulses 8 kHz off-resonance. Normal liver showed moderate magnetization transfer with an M_s/M_0 value of 0.67, with spleen showing less marked effects ($M_s/M_0 = 0.76$). Liver lesions gave similar values to normal spleen ($M_s/M_0 = 0.77$). Lesion-to-liver contrast was therefore improved on the scan with off-resonance radiofrequency compared with the standard gradient echo image. The authors point out that the magnetization transfer sequence may result in less lesion-to-liver contrast than standard heavily T_1 - or T_2 -weighted images, but may have improved signal-to-noise ratios and less motion artifact.

Outwater et al.¹² reported rather different results at the higher field strength of 1.5 T. In this study, a multislice gradient echo sequence ($TR = 400$ – 600 ms, $TE = 5$ ms, flip angle = 20°) with saturating pulses 1.5 kHz off-resonance was used to

study 26 patients with benign or malignant liver lesions. Using this protocol, liver and spleen showed similar magnetization transfer [M_s/M_0 (liver) = 0.64, M_s/M_0 (spleen) = 0.66]. Malignant lesions had an average value of 0.62, not significantly different from normal liver, with no resultant increase in lesion-to-liver contrast on magnetization transfer images. Primary hepatocellular carcinoma tended to give lower values (0.57) than metastases (0.64). In contrast, benign cysts and hemangiomas showed less magnetization transfer than normal liver, with improved lesion-to-liver contrast on the sequence with saturating radiofrequency pulses. Simple cysts demonstrated less signal loss than hemangiomas, presumably because the magnetization transfer effects in blood, although small, are greater than in simple fluids, and the presence of stromal tissue in hemangiomas. Measurements of the magnetization transfer effects allowed a separation between metastases and hemangiomas comparable to standard long TR , long TE (160 ms) T_2 -weighted spin echo sequences.

These two studies highlight the problems of comparing magnetization transfer results when different sequences, different saturating pulses, and different field strengths are used. Although quantitative measurements provide some tissue-specific information, at present magnetization transfer techniques are unlikely to replace standard imaging sequences in the liver. These studies are important, however, in that they will help in understanding tissue contrast generated by standard sequences in which magnetization transfer has been shown to play a role, for instance the fast T_2 -weighted spin echo sequences. These effects will be discussed in a later section. Despite further work in the abdomen^{38–41} results remain variable, and magnetization transfer does not yet have a major role in liver imaging. Although Wolff and Balaban's paper in 1989⁴ showed different magnetization transfer values in the renal cortex and medulla of the rabbit, there has been little work on

Figure 4 Twelve year old male with juvenile chronic arthritis. Coronal mildly T_2 -weighted spin-echo images ($TR = 2000$ ms, $TE = 16$ ms) (a) without and (b) with off-resonance irradiation. Signal from muscle is reduced and the synovium and joint fluid are more clearly visualized in (b). (Reprinted with permission from *Clinical MRI*)

abdominal organs other than the liver, or on the pelvis in humans.

7 MUSCULO-SKELETAL SYSTEM

The musculo-skeletal system seems to be ideally designed for magnetization transfer techniques. Muscle shows large magnetization transfer effects, fat virtually none. Cartilage shows large magnetization transfer effects, synovial fluid virtually none. Magnetization transfer can thus be used to increase the contrast between muscle and fat, and between cartilage and joint fluid (Figure 4).

Wolff et al.,¹¹ imaging the knees of normal volunteers at 1.5 T, showed that magnetization transfer improved the contrast between these pairs of tissues on a single-slice gradient echo sequence at all repetition and echo times and all but the lowest flip angle tested. The contrast was improved over standard T_2 -weighted spin echo sequences in a much shorter imaging time. Three-dimensional gradient echo sequences with high spatial resolution are ideal for studying the musculo-skeletal system, but often suffer from poor contrast. The same authors combined magnetization transfer with a 3D gradient echo sequence, again with excellent muscle/fat and cartilage/fluid contrast.

The strong magnetization transfer effect in articular hyaline cartilage appears to be due to collagen with little or no contribution from proteoglycans.⁴² It has been suggested that magnetization transfer may help identify early alterations in degenerating cartilage which displays focal fluid loss and increased collagen concentration. At 1.5 T using a 3D MT GRASS sequence, articular cartilage defects were shown more clearly than on routine sequences.⁴³ A second study at 0.5 T

using a T_1 -weighted spin echo MT sequence found no improvement over standard T_2 -weighted spin echo sequences.⁴⁴ Lenz et al. using a 3D FISP sequence at 0.2 T found that although saturating pulses improved cartilage/fluid contrast-to-noise ratios, meniscal tears were less well seen due to low signal-to-noise from cartilage.⁴⁵

Magnetization transfer has been used to study physiological and pathological effects in muscle. Magnetization transfer improves the contrast between active and inactive muscle after leg exercise on a gradient echo sequence at 0.26 T.⁴⁶ This effect may be due to the increase in extracellular water which is thought to occur with exercise.

The different effects on muscle and fat may allow an estimation of the fat content of muscles. Lamminen et al.⁴⁷ reported that magnetization transfer studies could give similar information to chemical shift imaging in the assessment of fatty infiltration of muscle in dystrophia myotonica.

Pathological tissue, both neoplastic and inflammatory, generally shows less magnetization transfer than normal muscle and may be seen with increased conspicuity on magnetization transfer sequences.⁴⁸⁻⁵⁰ In the study of muscles a magnetization transfer STIR sequence may be advantageous. Standard STIR sequences combining fat suppression with additive T_1 and T_2 contrast are sensitive to musculo-skeletal pathology. Fat suppression is advantageous in magnetization transfer imaging, as fat shows little magnetization transfer and retains a high signal. In addition, saturating pulses reduce the T_1 value of tissues demonstrating magnetization transfer such as skeletal muscle. In the MT-STIR sequence, the shortening of T_1 reduces the signal from normal muscle still further. At 0.15 T, the T_1 value of normal muscle becomes similar to that of fat and both tissues are nulled in an MT-STIR sequence. This can be used to obtain an angiogram of peripheral vessels.⁶ In imaging mus-

Figure 5 Thirty-eight year old male who received postoperative radiotherapy for a liposarcoma. Axial STIR ($TR = 2500$ ms, $TE = 30$ ms, $TI = 130$ ms) images of the calf (a) without and (b) with off-resonance irradiation. The signal from subcutaneous and marrow fat is nulled in both examinations. The signal from muscle is reduced in (b), highlighting the abnormal thickening and high signal of the stroma between the muscle compartments

culo-skeletal pathology, it may be preferable not to saturate normal muscle maximally but, as in the brain, to back off on the intensity of the saturating pulse to allow some signal to remain to improve overall signal-to-noise ratios and allow visualization of normal anatomy. Figure 5 illustrates the use of a MT-STIR sequence in a patient with inflammatory changes secondary to radiotherapy.

8 MAGNETIZATION TRANSFER EFFECTS IN CONVENTIONAL CLINICAL IMAGING

The discussion so far has concerned sequences in which saturating pulses are deliberately added to imaging sequences. Dixon et al.⁵¹ pointed out in 1990 that in multislice imaging radiofrequency pulses which are on-resonance for one slice will be off-resonance for adjacent slices and will result in incidental magnetization transfer effects. These were of the order of 10–20% for brain and muscle compared with fat and aqueous solutions. The effects are more pronounced in sequences with multiple refocusing pulses, such as rapid acquisition relaxation enhanced (RARE) or fast spin echo sequences^{52,53} and can result in alterations in tissue contrast; for instance, gray/white matter contrast-to-noise ratio increases with increasing slice number in proton density-weighted fast spin echo images as a result of magnetization transfer effects.⁵² Other pulses including fat saturation and presaturation pulses will have similar effects. In many instances these incidental magnetization transfer effects may be beneficial in lesion detection, as most pathological tissue shows less magnetization transfer than normal tissue, but the end result will depend on relative magnetization transfer effects and the starting signals of tissue.

As discussed earlier, hepatic neoplasms may not follow the general rule with similar magnetization transfer to normal liver. This is important when fast spin echo imaging is used in the abdomen.

9 CONCLUSIONS

Magnetization transfer studies have now been shown to be feasible in patients in a variety of body regions at a range of field strengths and have already had an impact on clinical imaging. Many imaging systems now routinely use magnetization transfer to improve the visualization of cerebral vessels in cranial magnetic resonance angiography. It is clear that magnetization transfer improves the appreciation of tissue enhancement by intravenous contrast agents and T_1 -weighted magnetization transfer sequences are being used in conjunction with gadolinium at a number of centers for brain and breast imaging. In other body areas, interesting effects have been observed, but the usefulness of magnetization transfer in clinical imaging remains largely unevaluated.

Quantitative measurements of magnetization transfer effects seem to be bearing fruit in the study of multiple sclerosis, but quantitation has been disappointing in other areas due to the overlap between different pathological tissues. More precise evaluation, for instance of rate constants, may provide more tissue-specific information.

We now recognise that incidental magnetization transfer plays a role in almost every imaging sequence. Knowledge of magnetization transfer will enable us to predict the effects, particularly in such sequences as fast spin echo and use them to our advantage.

Overhauser Effect Imaging of Free Radicals

David J. Lurie

University of Aberdeen, Aberdeen, UK

1 INTRODUCTION

Since its prediction by Overhauser and experimental verification by Carver and Slichter in 1953, the electronic Overhauser effect has had many and varied applications. This article will describe the combination of the electronic Overhauser effect with MRI in order to image the distribution of free radicals in phantoms, biological samples, animals and, potentially, humans.

Free radicals are defined as molecules with one or more unpaired electrons in their outer orbitals. Various free radicals are involved in normal metabolism, and changes in their concentration in the body have been associated with many diseases and pathological conditions. Furthermore, there exist free radicals which are stable in aqueous solution, and have the potential for use as contrast agents or tracers in biological and clinical MRI. Thus, a technique to image free radicals in vivo would have profound implications for biological and medical research as well as for clinical practice.

The electronic Overhauser effect is based on a combination of NMR and ESR on the same sample at the same time. It is also known as dynamic nuclear polarization (DNP). Applied to liquid samples, DNP involves the observation of the solvent's NMR signal while simultaneously irradiating one or more ESR resonances of a free radical solute. Under favorable conditions, the ESR irradiation can give rise to a large enhancement (increase in intensity) of the NMR signal, the amount of enhancement depending on a number of factors including the type and concentration of free radical and the strength of the ESR irradiation.

In the imaging experiment, the ESR irradiation is applied to the sample during the acquisition of an MRI image. The NMR signal is enhanced in parts of the sample containing free radical, and these regions exhibit greater intensity in the final image, revealing the distribution of the free radical. This combined imaging technique was first demonstrated in 1987, and was given the name proton electron double resonance imaging (PEDRI).¹ (The same technique has also been dubbed Overhauser MRI and DNP imaging by other workers in the field, but the acronym PEDRI will be used from now on.)

2 PERTINENT RESULTS FROM THE THEORY OF THE ELECTRONIC OVERHAUSER EFFECT

The theory of the electronic Overhauser effect and of DNP is well developed, and is covered elsewhere² and in excellent review articles on the subject.^{3,4}

The enhancement factor E in an electronic Overhauser effect experiment can be written:

$$E = 1 - \rho f s \frac{|\gamma_S|}{\gamma_I} \quad (1)$$

E can be defined as the ratio A_z/A_0 , where A_z and A_0 are respectively the NMR signal amplitudes obtained with and without ESR irradiation. γ_S and γ_I are the electronic and nuclear gyromagnetic ratios. ρ is the coupling factor, and depends on the nature of the interactions between the unpaired electrons and the NMR nuclei: $\rho = -1$ if the interactions are purely scalar, while $\rho = +\frac{1}{2}$ if dipolar interactions dominate (this is usually the case for small free radical molecules in solution).

The leakage factor, f , is an indication of the fraction of nuclear spin-lattice relaxation arising from the presence of the free radical in solution. It can be written as:

$$f = 1 - \frac{T_1}{T_1^0} \quad (2)$$

where T_1 is the spin-lattice relaxation time of the free radical solution, while T_1^0 is the spin-lattice relaxation time of the solution without free radical.

The saturation factor, s in equation (1), depends on the strength of the ESR irradiation and on the ESR relaxation times. It can be written as follows:

$$s = \frac{1}{n} \left(\frac{\gamma_S^2 B_2^2 \tau_1 \tau_2}{1 + \gamma_S^2 B_2^2 \tau_1 \tau_2} \right) \quad (3)$$

where B_2 is the rf magnetic field strength of the ESR irradiation, τ_1 and τ_2 are the electronic longitudinal and transverse relaxation times, and n is the number of lines in the free radical's ESR spectrum.

Assuming $\rho = \frac{1}{2}$, and considering proton NMR (so that $|\gamma_S/\gamma_P| = 658$), we can combine and rearrange equations (1)–(3) into the form:

$$\frac{1}{1-E} = \frac{n}{329} \left(1 + \frac{1}{\alpha P} \right) \left(1 + \frac{1}{kcT_1^0} \right) \quad (4)$$

where P is the power of the ESR irradiation and α is a constant, k is the longitudinal NMR relaxivity of the free radical of interest and c is its concentration. The terms in parentheses are respectively the reciprocals of the saturation and the leakage factors.⁵

If we assume that $n=3$ (as is the case with nitroxide free radicals), then we can predict the maximum enhancement factor $E^{\max} = -109$, obtained with infinite ESR irradiation power (causing total saturation of the ESR resonance) and with a highly concentrated solution, giving a leakage factor of unity. (A negative value of E means that the phase of the NMR signal obtained while irradiating the ESR resonance is altered by π radians compared with the normal NMR signal, while the ratio of the signal intensities is $|E|$.) Enhancements as large as $E^{\max}$ are not observed in practice, but it is nevertheless possible to observe enhancement factors of -50 or -60 depending on the system under study. In general, the type of free radical has a strong influence on the achievable enhancement factor: a free radical with few ESR lines (n), each of which is narrow (long τ_2), and which exhibits high NMR relaxivity (k) will, accord-

ing to equations (1), (3), and (4), result in a large enhancement factor at a given level of ESR irradiation.

3 PEDRI TECHNIQUES

3.1 Magnetic Field Strength

Most clinical MRI is carried out at field strengths of 0.5 T or above. Unfortunately, the ESR frequency even at 0.5 T is greater than 14 GHz, much too high to penetrate into ionic samples due to dielectric losses. In order to achieve sufficient penetration of the ESR irradiation into small animals or human limbs, its frequency must be less than 300 MHz or so, corresponding to magnetic field strengths of 10 mT and below: this is the range of magnetic fields which must be used in biological PEDRI experiments. Furthermore, it can be shown that the ESR irradiation power required to achieve a given enhancement is proportional to the volume of the sample and to the square of the ESR frequency used; it is therefore necessary to use frequencies below 300 MHz in order not to overheat the sample under study.

3.2 PEDRI Pulse Sequences

Apart from the necessity of using static magnetic fields of 10 mT or less, and the addition of hardware to irradiate the ESR resonance (described in Section 4.2 below), PEDRI uses standard MRI hardware and virtually standard software. Any MRI pulse sequence can be converted to a PEDRI pulse sequence by the addition of one or more periods of ESR irradiation. Figure 1 shows an example of a simple PEDRI pulse sequence based on a gradient echo MRI sequence. Here, the basic spin warp pulse sequence is preceded by a period of ESR irradiation of length T_{ESR} . Since the nuclear magnetization builds exponentially toward its enhanced equilibrium value upon switching on the ESR irradiation, with a time constant equal to T_1 , it is not necessary to apply the ESR irradiation continuously. However, if it is desired to

maximize the enhancement, one must ensure that T_{ESR} is longer than about three times the longest T_1 in the sample. Similarly, the enhanced magnetization decays at a rate governed by T_1 after the ESR irradiation is removed, so the time between the end of ESR irradiation and the NMR detection pulse should be short.

While the intensity in a PEDRI image depends on the local concentration of free radicals, unless the enhancement factors are very high it is not easy to differentiate free radical-containing regions from those which would normally exhibit high intensity in the MRI image. Thus, it is useful to collect two images of the same slice in the object under study: one with, and one without, ESR irradiation. Subtraction of the two image data sets then yields a ‘difference’ image in which nonzero image intensity indicates the presence of a free radical. The complex data sets (rather than the image intensities) should be subtracted in order to account correctly for negative values of the enhancement factor. It is convenient to use an interleaved pulse sequence, each alternate NMR excitation being preceded by ESR irradiation, with two signals being recorded at each phase-encoding view, contributing separately to ‘with ESR’ and ‘without ESR’ images.⁵

With low concentrations of free radical (such that $kc \ll 1/T_1^0$), the image intensity in a ‘difference’ image is proportional to the free radical concentration, but the constant of proportionality will differ between samples (or tissues) with different T_1^0 values (e.g. liver and kidney) by virtue of equation (4). In samples with short T_1^0 , the inherent relaxation pathways are stronger in comparison with the free radical related dipolar interactions than in samples with long T_1^0 , and result in lower enhancement factors for any given free radical concentration.

3.3 Field Cycled PEDRI

The quadratic dependence of the ESR irradiation power on the ESR frequency means that one would ideally perform PEDRI experiments at magnetic fields well below 10 mT. Very low magnetic fields are required also for PEDRI experiments on large animals or the human abdomen, since the penetration depth of electromagnetic radiation at 250–300 MHz is not sufficient to provide uniform excitation in these cases. While it is certainly possible to reduce the ESR irradiation frequency to 100 MHz (say) by lowering the magnetic field B_0 to 2.5 mT, such a reduction in B_0 would have a catastrophic effect on the signal-to-noise ratio (S/N) of the MRI experiment, with a consequent reduction in sensitivity and image quality. The combination of PEDRI with magnetic field cycling enables the rf power requirement to be reduced (while maintaining enhancement) without reducing the S/N.⁶

In a field cycled NMR pulse sequence, the applied magnetic field B_0 is not constant, but is switched between a number of levels (usually three), each of which has its effect on the spin system.⁷ The field cycled PEDRI (FC-PEDRI) pulse sequence (Figure 2) commences with the polarization period at field strength B_0^P , during which the nuclear magnetization reaches thermal equilibrium. The magnetic field is then reduced rapidly to B_0^E where it is held for the duration of the evolution period, when the ESR irradiation is applied at the appropriate frequency and power. The Overhauser enhancement occurs during this period. Finally, the magnetic field is increased again before

Figure 1 The basic PEDRI pulse sequence. A period of ESR irradiation, shown as RF^{ESR} , duration T_{ESR} , precedes the normal MRI sequence (shown here as a gradient echo, spinwarp sequence). The sequence repetition time is TR . G_s , G_t , and G_c are the orthogonal selection, readout and phase-encoding gradient waveforms, respectively

Figure 2 Field cycled PEDRI pulse sequence, showing the polarization period at magnetic field B_0^P , the evolution period at B_0^E and the detection period at B_0^D . The ESR irradiation is applied during the evolution period, at a frequency and power appropriate to B_0^E . The S/N is largely determined by the magnetic field applied during the detection period

the start of the detection period at B_0^D , during which the NMR detection pulse(s) and imaging magnetic field gradients are applied as usual. The time to switch between B_0^E and B_0^D must be as short as possible to minimize the decay of the enhanced magnetization following the end of the ESR irradiation. The S/N depends on the relative timing of the three periods, and on the magnetic fields, but especially on the value of B_0^D . By judicious selection of the sequence parameters it is possible to reduce the specific applied rf power while maintaining the enhancement, without sacrificing the S/N of the experiment.

4 HARDWARE REQUIREMENTS

As PEDRI makes use of virtually standard MRI techniques, most of the hardware required is identical, and will not be discussed here (see *Low-Field Whole Body Systems*). The two areas where differences arise between standard MRI and PEDRI are the magnet and the rf coil assemblies.

4.1 The Magnet

PEDRI does not place any more demand than conventional MRI on the specification of the magnet. It has already been mentioned that PEDRI requires the use of fields of 10 mT or less; while there is no reason why one could not use a superconducting magnet to generate the static field, it is likely to be more convenient (and cheaper) to use resistive (or permanent) magnets.

Not surprisingly, FC-PEDRI does require the use of specialized magnet and power supply hardware. The magnetic field applied during the detection period must be as homogeneous and as stable as required by conventional MRI. Because of the broad nature of ESR resonances (say 0.2 mT at a field strength of 10 mT for a typical nitroxide free radical), the stability and

homogeneity can be relaxed considerably during the evolution period, as indeed they can during the polarization part of the pulse sequence since small local differences in the initial magnetization have negligible effect on the image. The final requirement is the necessity to switch magnetic fields between levels in a time considerably less than the T_1 of the sample under study. In biological studies, one would not wish to switch between the evolution and detection magnetic fields in more than 50 ms, to avoid losing valuable enhanced magnetization.

There are two basic methods of field cycling.⁶ In the first, direct method, a single resistive magnet and power supply is used, the current through the magnet windings being altered in order to change the magnetic field at the sample. The electrical characteristics of the magnet and power supply must be such that the current can be changed sufficiently rapidly, and the magnetic field must be accurately and repeatably held constant during the detection period.

The second method, called 'field compensation', makes use in its simplest incarnation of two coaxial magnet coils, with separate power supplies. The large primary magnet is supplied with a constant current to generate B_0^D , with good homogeneity and stability. The smaller secondary coil, which surrounds the sample under study, generates a field parallel or antiparallel to the primary coil's, and the current is altered during the pulse sequence in order to achieve field cycling.⁵⁻⁷

Field compensation is probably to be preferred over direct field cycling, because only the stable, homogeneous primary magnet is energized during the critical detection period: the current in the secondary coil is 'clamped' to zero during this part of the pulse sequence, and this is inherently simpler and more reliable than trying to reproduce precisely the same non-zero current each cycle. This advantage is at the expense of some complexity, however, since two magnets and two power supplies are required, and there is inevitably some degree of mutual inductance between the two coils which may destabilize the detection magnetic field. Replacing the primary coil by a suitable permanent magnet offers the possibility of a simpler design, but care must be taken to avoid eddy currents in the magnet structure which might scupper attempts to cycle rapidly. Whichever method is chosen, field cycling on a whole body scale is a considerable technical challenge, since the magnetic field energy (which must be removed and replaced every half cycle of the pulse sequence) increases in proportion to the magnet volume. Nevertheless, the offer of high enhancements and good S/N, without high rf power is extremely appealing, and is probably the only means of detecting micromolar concentrations of free radicals. Lurie et al. have recently constructed a large-scale FC-PEDRI imager, based on a whole-body 59 mT permanent magnet with a co-axial resistive magnet for field-compensation.⁸

4.2 ESR Irradiation Hardware

Perhaps the most significant difference between MRI and PEDRI hardware is the need to deliver a continuous or pulsed ESR irradiation in the latter technique. The apparatus used to generate the ESR irradiation consists basically of a signal generator, power amplifier and tuned coil or resonator.

The first two items will normally be off-the-shelf commercial units, the specification of which is largely determined by the

magnetic field strength being used (ESR frequency) and the size of the sample (irradiation power). As ESR resonances are rather broad (see Section 4.1 above) the signal generator need not be especially stable. However, the ease of adjustment of frequency and amplitude offered by synthesized frequency generators make these instruments particularly suitable.

The most specialized item of hardware is undoubtedly the coil or resonator used to apply the ESR irradiation to the sample under study. The design of the ESR resonator is complicated by the fact that it is also necessary in PEDRI to excite the NMR resonance of the sample and to detect NMR signals, and the NMR coil and ESR resonator should be designed together as an integrated structure. Ideally, the quality- and filling-factors of both the NMR coil and the ESR resonator should be optimized. In practice, the design is inevitably a compromise, and optimization of the NMR coil should take precedence over the characteristics of the ESR resonator. (Loss of S/N caused by reduced filling factor or quality factor of the NMR coil can only be recovered by signal averaging, while a compromise based on reducing the ESR resonator's filling factor will only result in a greater power requirement from the ESR irradiation power amplifier.) One design of NMR/ESR coil assembly for use with vertical-field magnets uses a solenoidal NMR coil with a coaxial, external ESR resonator based on the design of Alderman and Grant.⁹

5 APPLICATIONS AND POTENTIAL OF PEDRI

PEDRI is a relatively young technique, with (at the time of writing) only a small number of sites contributing to its development. The potential applications of the technique are, however, quite considerable, particularly if the technology can be developed to apply the technique on a whole body scale. Applications can be divided into two groups: those involving the detection of exogenous (i.e. externally introduced) free radicals and those which aim to image the distribution of endogenous free radicals. The latter is by far the most challenging (and potentially rewarding).

There are many endogenous free radicals which have been implicated in the disease process. Two of the most important are hydroxyl ($\cdot\text{OH}$) and nitric oxide ($\text{NO}\cdot$); however, neither is amenable to direct detection in the body by magnetic resonance, because of their short lifetimes and unsuitable ESR characteristics. Nevertheless, it may be possible to detect and image these and other endogenous radicals by combining PEDRI with a chemical stabilization technique called spin trapping.¹⁰ In this method, a spin trap molecule (not itself a free radical) is first dissolved in the system under study. If short-lived free radicals are subsequently formed near a spin trap molecule, they may be 'trapped', forming a longer-lived free radical called a spin

Figure 3 A set of PEDRI 'difference' images through the abdomen of a supine, 350 g, anesthetized Sprague-Dawley rat, following the administration of a 300 mM solution of bicarbonate-buffered PCA nitroxide free radical at a dose of 0.8 mmol per kg of body weight. Image matrix size: 64×64 ; field-of-view 10×10 cm; slice thickness 2 cm; field strength 10 mT; ESR irradiation frequency 238.7 MHz. An interleaved pulse sequence was used, with an overall sequence repetition time (TR) of 2000 ms, and $T_{\text{ESR}} = 300$ ms. Image 1 was collected 1 min after administration of PCA, and the remaining images were collected at 6, 11 and 16 min postinjection respectively. The labels are: (a) liver; (b) right kidney; (c) left kidney

adduct which can then be detected. The imaging by PEDRI of spin trapped hydroxyl free radicals formed in a chemical model system has already been demonstrated,¹¹ and work is underway at the time of writing to detect free radicals generated in a variety of biological systems.

The imaging of exogenous free radicals in vivo also offers the possibility of interesting applications. Here, stable free radicals are injected and used as 'contrast agents', PEDRI images being collected to follow the progress of the free radical through the body. (There is a class of compounds known as nitroxide free radicals which are virtually stable in aqueous solution, and whose chemical properties make them potential candidates for PEDRI studies.)

The first in vivo PEDRI studies were carried out in 1990. Grucker administered an intraperitoneal injection of nitroso disulfonate (Fremy's salt) to an anesthetized rat, and imaged the distribution of the free radical solution in the animal's peritoneal cavity, thus demonstrating the feasibility of in vivo PEDRI experiments.¹² Unfortunately, although Fremy's salt has very narrow ESR lines, resulting in large enhancement factors, it is too unstable and toxic for intravenous injection. Lurie et al. injected anesthetized rats intravenously with a solution of a nitroxide free radical (3-carboxy-2,2,5,5-tetramethylpyrrolidine-1-oxyl or PCA), and were able to observe by PEDRI the clearance of the free radical through the animal's liver and kidneys.¹³ Subsequent analysis of images collected over the course of 30 min postinjection allowed pharmacokinetic data to be obtained.⁴ Figure 3 shows a set of images from the author's laboratory demonstrating the clearance of PCA through the kidneys of a rat; this type of study gives information on the functionality of the kidneys.¹⁴ Recent studies of normal and diseased rats have provided useful information in a model of analgesic nephropathy.¹⁵ Nitroxide free radicals are extremely versatile compounds, and can be 'labeled' onto larger molecules, offering the possibility of 'tracer' studies by targeting contrast agents to specific tissues. A contrast agent with a single narrow ESR line is being developed by industry for use with PEDRI; it has already been used to produce very-high-resolution images of rats.¹⁶

Another potential application of PEDRI using exogenous free radicals is localized in vivo oximetry.^{1,17} It is well known that oxygen in solution broadens the ESR lines of nitroxide free radicals. Broad ESR resonances are more difficult to saturate, resulting in lower enhancement factors in the PEDRI experiment. The main difficulty is to differentiate between low enhancement caused by high oxygen concentration and low enhancement caused by low free radical concentration. Research is currently underway to address this problem.

PEDRI is developing into a useful technique for the study of free radicals in vivo. Good results have been obtained in studies of exogenous free radicals in small animals, and these experiments are starting to give useful results on organ function. PEDRI is easier to implement than ESR imaging and produces images with better spatial resolution (see *EPR and In Vivo EPR: Roles for Experimental and Clinical NMR Studies*; also *In Vivo ESR Imaging of Animals*).¹⁸ At the time of writing, the sensitivity of PEDRI is such that it ought to be able to detect spin-trapped endogenous free radicals in model systems (free radicals at concentrations of 5–10 μM can be detected), offering a novel research tool in biology and medi-

cine. Current research aims to improve the sensitivity, for example by field cycling to higher magnetic fields.

The technology to apply PEDRI to human-sized samples is currently being developed; its actual use in human subjects depends to a large extent on the development of suitable contrast agents (and perhaps spin traps) by the pharmaceutical industry.

Susceptibility and Diffusion Effects in NMR Microscopy

Paul T. Callaghan

Massey University, Palmerston North, New Zealand

1 INTRODUCTION

NMR microscopy concerns the imaging^{1,2} of small-scale samples at high spatial resolution.³⁻⁷ Resolution in NMR imaging is limited by the reduction in intrinsic signal-to-noise ratio as the voxel (volume element) size is decreased.^{7,8} In NMR microscopy these elements will typically have at least two dimensions (the ‘pixel’ or image picture element) smaller than 100 μm . Most microscopy experiments are carried out using vertical bore magnets with fields in excess of 5 T. These fields, coupled with the inevitable heterogeneity of the sample, lead to significant susceptibility-related line broadening and consequent image artifacts. Furthermore, at such high spatial resolution the effects of molecular self-diffusion become significant⁹ leading to profound effects in the image when the distance moved by the molecules over the image acquisition time is comparable to the voxel dimensions. In this article we examine some of the influences arising from susceptibility and diffusion and show how they may be used to profitable effect.

The disturbance to the local magnetic field near a boundary between two regions of differing diamagnetic susceptibility, is well-known in large-scale MRI.¹⁰ The parameter of significance in the associated image distortion is scale-independent, and given by $\gamma B_0 \Delta\chi / 2\pi \Delta f$, where Δf is the acquisition bandwidth, $\Delta\chi$ is the local susceptibility change and B_0 is the polarizing field. Susceptibility effects in imaging have recently featured prominently in clinical MRI studies of the human brain, where it has been shown that capillary blood flow associated with neural activity can be directly observed.¹¹⁻¹⁶ The contrast in this so-called ‘functional’ MRI is believed to derive from changes in paramagnetic susceptibility associated with transitions in the oxygenation state of hemoglobin. While noting their importance, we shall not deal directly with such effects in this article. One reason that susceptibility inhomogeneity effects are especially important in NMR microscopy is that the desire to optimize signal-to-noise ratios leads, customarily, to use of large B_0 and, in some cases, small Δf .

By contrast with susceptibility effects, resolution and sensitivity limitation due to molecular self-diffusion is significant only in microscopy. While the effects of self-diffusion can be subtle, as a ‘rule of thumb’, the parameter of significance is $\Delta x_{\text{diff}} / \Delta x_{\text{pixel}}$, where Δx_{diff} is the rms displacement of the spins over the signal acquisition period and Δx_{pixel} is the pixel dimension. Given that acquisition periods are usually on the order of several milliseconds, Δx_{diff} is on the order of 10 μm .

A clue to the presence of local field variations is given by comparing images obtained using gradient and spin echoes. Examples of these respective pulse sequences are shown in

Figure 1. In the spin echo sequence, any dephasing of spin magnetization caused by inhomogeneity in the magnetic field is refocused at the center of the signal acquisition while for the gradient echo such dephasing is allowed to evolve relentlessly, leading to severe image attenuation in regions where the local field variation is strong. It is important to note that such an influence arises from the static field distribution and is associated with the inhomogeneous broadening of the NMR line. However molecular motion leads to fluctuations in this field in a manner which leads to irreversible decay of magnetization, a relaxation effect which contributes to homogeneous broadening. Both influences are generally present in NMR microscopy and are dealt with in turn in the following sections of this article.

2 STATIC SUSCEPTIBILITY EFFECTS

2.1 Gradient and Spin Echoes

When a heterogeneous sample is placed in a uniform magnetic field, local field distortions are most apparent near susceptibility boundaries. By applying Maxwell’s equations under the usual boundary conditions it is possible to compute $\Delta B_0(\mathbf{r})$, the difference in magnitude between the local field and the average magnetic field over the sample. The influence of the local field variations can be seen by adding the local precession frequency offset, $\gamma \Delta B_0(\mathbf{r})$, to that which arises from the magnetic field gradient.^{7,17} Thus the signal acquired under the influence of a steady gradient G applied for a time t is given by

Figure 1 Imaging pulse sequences showing the timing of gradient and rf pulses in the spin warp scheme for (a) spin echo and (b) gradient echo refocusing respectively. Note that the delay in echo formation following excitation is given by TE

$$S(t) = \iiint \rho(\mathbf{r}) \exp\{i\gamma[\mathbf{G} \cdot \mathbf{r} + \Delta B_0(\mathbf{r})]t\} d^3r \quad (1)$$

a result which leads to a Fourier pair

$$S(\mathbf{k}) = \iiint \rho(\mathbf{r}) \exp[i\gamma\Delta B_0(\mathbf{r})t] \exp(i2\pi\mathbf{k} \cdot \mathbf{r}) d^3r \quad (2)$$

$$\rho_1(\mathbf{r}) = \iiint S(\mathbf{k}) \exp(-i2\pi\mathbf{k} \cdot \mathbf{r}) d^3k \quad (3)$$

where $\mathbf{k}$ is the usual product $(2\pi)^{-1}\gamma\mathbf{G}t$. Inverse Fourier transformation of $S(\mathbf{k})$ is used to reconstruct the apparent spin density function, $\rho_1(\mathbf{r})$, and it is clear from equations (2) and (3) that the presence of the term involving $\Delta B_0(\mathbf{r})$ will cause $(\rho_1(\mathbf{r}))$ to deviate from the ideal result, $\rho(\mathbf{r})$. The distorting influence of this local field depends specifically on the pulse sequence used to obtain the image.

Consider the gradient echo and spin echo sequences of Figure 1. The center of ' $\mathbf{k}$ -space', which determines the overall image intensity, occurs at the center of the echo half-way through the read gradient. For the spin echo, the dephasing effect of the spread in $\Delta B_0(\mathbf{r})$ over each pixel is refocused to zero at $\mathbf{k} = 0$, whereas it remains to produce attenuation in the gradient echo, thus providing a nice 'signature' for local field effects. An example of how this sensitivity of the gradient echo to local fields can be used to good advantage is shown in Figure 2 where a spin echo and gradient echo image from the same plant stem (*Stachys sylvatica*) are compared.¹⁸ In the gradient echo image, dephasing of water proton magnetization at the boundaries of cells in the parenchyma tissue causes each cell to be highlighted in sharp relief.

2.2 Image Distortion

Despite the fact that static susceptibility attenuation effects are removed at the centre of $\mathbf{k}$ -space in spin echo imaging, perturbations to the local magnetic field will still produce a residual distortion of the image. In considering this effect we will concentrate on the commonly used spin warp^{19,20} variant of Fourier imaging in which a fixed duration phase gradient (G_y) is applied for a time t_y . For such a raster equation (1) may be rewritten,^{7,17}

$$S(k_x, k_y) = \iint \rho(x, y) \exp\{i2\pi k_x[x + \Delta B_0(x, y)/G_x]\} \times \exp(i2\pi k_y y) \exp[i\gamma\Delta B_0(x, y)t_y] dx dy \quad (4)$$

The effect of the field offset in equation (4) is to cause each element of the original object at (x, y) to contribute to a single element in the final image displaced from the original position to $[x + \Delta B_0(x, y)/G_x, y]$ and to acquire a local phase shift given by $\exp[i\gamma\Delta B_0(x, y)t_y]$. Generally this phase shift, which develops during the phase-encoding period, is removed by calculating a final modulus image and, with few exceptions,²¹ its effect can generally be ignored. The read gradient element displacement, $\Delta B_0(x, y)/G_x$, is common to all pulse sequences (for example spin warp and projection-reconstruction) which utilize frequency encoding. Pure phase-encoding sequences are therefore useful in avoiding susceptibility distortions but, while intrinsically as efficient as other methods, they incur a severe penalty in image acquisition time.¹⁹

The condition for avoiding image distortion in pulse sequences using frequency encoding is $\Delta B_0(x, y)/G_x \ll \Delta x$ or $(\Delta x)^{-1} \Delta B_0(x, y) \ll G_x$. This states that the local field offset should be less than the variation in applied (gradient) field

Figure 2 Gradient and spin echo ^1H NMR images obtained from the stem of *Stachys sylvatica*, in which the slice thickness was 1 mm and the imaging bandwidth was 40 kHz in each case.¹⁵ In the 256×256 pixel gradient echo image ($TE = 7.8$ ms) dephasing of magnetization occurs due to local fields near the cell boundaries

Figure 3 Schematic diagram of the local field $\Delta B_0(x, y)$ and associated gradient $G_x(x, y)$ for the glass rod system pertaining to Figure 4. The black and white lobes correspond to oppositely signed regions of field and gradient

across a single pixel, a condition which points to the desirability of large magnetic field gradients. An example of susceptibility-induced image distortion is shown in Figures 3 and 4, in which aqueous solutions surrounding a small glass rod are imaged at two different read gradient strengths. The applied transverse polarizing field induces a local offset field around the central glass rod which varies as^{17,22}

$$\Delta B_0(x, y) \approx \frac{\chi_{m1} - \chi_{m2}}{2} \frac{a^2}{r^2} \left(\frac{2y^2}{r^2} - 1 \right) B_0 \quad (5)$$

where y is taken to be the direction of the polarizing field, B_0 , and $r = (x^2 + y^2)^{1/2}$. χ_{m2} and χ_{m1} are the diamagnetic susceptibilities of the glass rod and the medium outside the glass rod respectively. $\Delta B_0(x, y)$ has both positive and negative ‘lobes’ around the glass rod as shown schematically in Figure 3. Consequently spins are shifted either ‘upfield’ or ‘downfield’ in the subsequent reconstruction, leading to the classic arrowhead distortion. Note that in Figures 4(a) and (b), the polymer proton signal in a polyethylene oxide solution is observed by means of a chemical shift selective rf excitation pulse. For such a large molecule diffusive effects are insignificant. By contrast, in Figures 4(c) and (d) the corresponding water images are shown. Here molecular diffusion plays a major role.

3 READ GRADIENTS AND DIFFUSION

3.1 Diffusive Relaxation

The translational diffusion of molecules in the presence of a spatially dependent magnetic field induces phase shifts in the spin transverse magnetization which cause signal attenuation. In imaging experiments such attenuation arises from both the imaging gradients and the local field variations caused by susceptibility inhomogeneity, and both effects can be highly significant in NMR microscopy.^{21,23}

For a steady uniform gradient G applied for a time duration t , diffusive attenuation is described by the factor $\exp(-\frac{1}{3}\gamma^2 G^2 D t^3)$ whilst the attenuation for an echo under two closely spaced gradient pulses of duration $\frac{1}{2}t$ and separation $t' \approx \frac{1}{2}t$, is given by $\exp(-\frac{1}{12}\gamma^2 G^2 D t^3)$. In the spin echo variant

of spin warp imaging shown in Figure 1(a), the echo amplitude, as measured at $k_x = 0$, suffers a diffusive attenuation at the center of k -space because of the two read gradient pulses. Ignoring the somewhat subtler effects of phase gradient diffusive attenuation,²¹ and assuming a minimum possible echo time, we can write the attenuation factor as $\exp(-\frac{4}{3}\pi^2 k_x^{\max 2} D N T)$, where $k_x^{\max}$ is the maximum value in the k_x raster, $(2\pi)^{-1} G_x (\frac{1}{2} N T)$, and $N T$ is the echo signal acquisition time, T being the reciprocal of the bandwidth, Δf . Clearly the effect of diffusive relaxation increases as the sampling bandwidth decreases or the number of pixels increases.

One important point to note is that in NMR microscopy experiments, a simple spin echo experiment, of the type shown in Figure 1(a), cannot be used to measure T_2 by simply varying TE , since such a measurement would be strongly affected by diffusive attenuation in the read gradient.²⁴ In consequence, it is essential to use a precursor spin echo or Carr–Purcell–Meiboom–Gill^{25,26} (CPMG) pulse sequence to allow T_2 relaxation contrast before the read gradient is applied if the influence of diffusive attenuation in the read gradient is to be avoided. Such a pulse sequence is shown in Figure 5.

3.2 Special Contrasts: Edge Enhancement and Read Gradient Null Points

Figure 6 shows how the intensity of an image obtained at microscopic resolution can reduce dramatically because of diffusive relaxation when the numbers of pixels are increased from Figures 6(a) to 6(b). While such relaxation clearly limits the available resolution, it can also be deployed to useful effect, as apparent in the higher resolution image where attenuation effects are particularly severe. Near the walls, where the molecular diffusion is impeded, the attenuation is less severe and bright edges appear.^{24,27} A similar effect is apparent in Figure 6(c) where an image of a cylindrical capillary of water is shown. Here crescent-shaped edges appear where molecular diffusion is impeded in the direction of the read gradient. These ‘edge-enhancement’ effects indicate the usefulness of diffusive relaxation as a means of indicating restrictions to Brownian motion.

The bright edge features apparent in Figure 6 arise because of modulation in the local self-diffusive coefficient under imaging conditions where strong diffusive relaxation is expected because of the applied read gradient. Another form of bright feature can occur when susceptibility-related fields modulate the net local gradient. As a result of such gradient superposition, the total gradient at any point may be either larger or smaller than the applied read gradient thus leading to attenuation enhancement or reduction. In particular, at well-defined sites, gradient null points can occur, provided that the read and local gradients are comparable in magnitude and opposite in direction. This cancellation should result in sharp, point-like, bright spots in an image where the read gradient otherwise causes signal attenuation. By contrast the regions where the read and local gradients add constructively will be somewhat larger, leading to diffuse features where additional attenuation is observed. These effects are apparent in Figure 4(d). It is interesting to note that whereas the local field ΔB_0 has two-fold symmetry, the symmetry of the x - and y -components of the gradient in the local field is three-fold, leading to the bright spots being arranged in a triangular array.²¹

Figure 4 Proton NMR images from the aqueous solution surrounding a glass rod (diameter $370\ \mu\text{m}$) inserted inside a cylindrical capillary (i.d. $1600\ \mu\text{m}$). The susceptibility difference is $0.7\ \text{ppm}$ and the polarizing field B_0 is transverse to the capillary. (a) and (b) show images obtained from the polymer proton signal in the sample for which diffusive effects are absent, at $20\ \text{kHz}$ and $1\ \text{kHz}$ bandwidth respectively. The arrowhead shape in (b) is symptomatic of the local field distortion produced by the glass rod through the center of the sample. (c) and (d) are the corresponding images for a pure water sample. In (d) bright spots appear where the gradient in the local field, ΔB_0 , precisely cancels the read gradient (G_x). (Reproduced by permission from Callaghan et al.²¹)

The usefulness of gradient null points is suggested in Figure 6(c), where we observe bright spots in the water. These disappear when microfiltered water is used, suggesting that the bright regions are associated with local dust particles, too fine to be observed directly.²¹ The local field thus provides a means of indirect detection via a local modulation of diffusive attenuation. By this means NMR microscopy can be made sensitive to more delicate structural features than might be expected from the usual sensitivity limits to pixel resolution.

4 DIFFUSION IN LOCAL GRADIENTS

4.1 Fast and Slow Exchange

The read gradient and acquisition bandwidth conditions which lead to strong diffusive attenuation are a somewhat pathological case in which nonetheless intriguing and useful contrast can arise. Most NMR microscopy experiments will

Figure 5 Imaging pulse sequence for which the spatial encoding is preceded by an n -loop CPMG rf pulse train, thus imparting T_2 contrast to the image. This sequence avoids diffusive attenuation artifacts in T_2 (due to the read gradient) as TE is increased, in contrast with the standard echo sequence of Figure 1. This sequence can also be used to distinguish local (susceptibility-related) gradient contributions to T_2

however be performed using values of the factor $\exp(-\frac{4}{3}\pi^2 k_x^{\max 2} DNT)$ close to unity. Under these conditions, we need only consider the diffusive relaxation effects arising from the local gradients, $\nabla [\Delta B_0(r)]$, due to susceptibility inhomogeneity. In a wide class of examples this heterogeneity results in a fluctuation of the local Larmor frequency [with rms frequency range $(\Delta\omega_0^2)^{\frac{1}{2}}$] as the molecules diffuse. Associated with this effect will be an average fluctuation correlation time, τ_c , corresponding to the time taken for a spin to diffuse over

the distance associated with the local field variation. Given these parameters, two regimes, fast exchange and slow exchange, may be defined according to $\Delta\omega_0^2 \tau_c^2 \ll 1$ or $\Delta\omega_0^2 \tau_c^2 \gg 1$.

In slow exchange the spin echo attenuation at time $2t$ will be given by^{7,28,29} $\exp(-\frac{2}{3}\Delta\omega_0^2 \tau_c^{-1} t^3)$. Slow exchange also corresponds to inhomogeneous broadening in the spectrum, an effect which is immediately apparent in the different behaviors of spin and gradient echoes. In fast exchange, where hom-

Figure 6 (a) ^1H NMR image of a stack of seven pentane-filled microcapillaries obtained with an acquisition bandwidth of 20 kHz. In (a) 128×128 pixels are used while in (b) a 256×256 array is used. Note the severe diffusive attenuation consequent on resolution increase and the bright edges due to inhibition of Brownian motion near the walls. In (c) a similar effect is apparent in a 256×256 image of a 1.6 mm i.d. capillary of water under the conditions $\Delta x_{\text{diff}} = 1.4 \Delta x_{\text{pixel}}$. Bright crescent features are apparent near the walls where diffusion along the direction of the read gradient is impeded. Note the appearance of bright features in the water which we ascribe to the influence of dust particles in which local gradients arising from susceptibility inhomogeneity cancel the read gradient, leading to reduced diffusive attenuation. (Reproduced by permission from Callaghan et al.²⁴)

Figure 7 Images of the same water sample used to obtain the images shown in Figure 4 but using a preceding CPMG pulse sequence to maintain transverse magnetization before position-encoding the image. In (a) $t = 113$ ms and $n = 1$ whilst in (b) $t = 113$ ms and $n = 10$. Note the strong diffusive relaxation in the vicinity of the local susceptibility gradient surrounding the rod in (a) and its removal on reducing the CPMG pulse spacing in (b). (Reproduced by permission from Forde¹⁸)

ogenous broadening applies, the relaxation is given by $\exp(-\Delta\omega_0^2\tau_c t)$.

In NMR microscopy, where intrinsic sensitivity limits resolution to the micrometer scale, slow exchange conditions are of predominant interest. Given some correlation length ξ in the local field variation, τ_c is of order ξ^2/D . Typical susceptibility inhomogeneities of a few parts per million lead to spectral fluctuations of a few kilohertz at most, while fluctuations of less than a few hertz will be irrelevant because of the intrinsic NMR linewidth associated with background field inhomogeneity or T_2 relaxation. With this likely range of $(\Delta\omega_0^2)^{1/2}$, fast exchange conditions will only apply for correlation times below 10 ms, corresponding to correlation lengths below a few micrometers in the case of freely diffusing water molecules. This means that heterogeneity on a scale larger than the pixel dimension will generally be associated with the slow exchange criterion. For example, when susceptibility variations arise from bonding surfaces with radii of curvature much larger than a few micrometers, the broadening is inhomogeneous and slow exchange applies.

The t^3 dependence of the relaxation exponent provides a clear signature for slow exchange. Another indication is provided by the pulse spacing dependence of echo attenuation in a CPMG pulse train (see Figure 5) in which the time t is separated into n periods each of time (t/n) by the 180° rf pulses. By this means t^3 is reduced to $n(t/n)^3$, thus drastically reducing the attenuation. Figure 7 shows the attenuation caused by molecular self-diffusion of water molecules in the vicinity of the glass rod, using the same sample depicted in the images of Figure 4, but with a pulse sequence employing a CPMG pulse train which precedes the imaging gradients. In Figure 7(a) a single spin echo loop is used ($n = 1$) and strong diffusive attenuation is apparent around the entire perimeter of the rod, while in

Figure 7(b), where $n = 10$, the attenuation is absent. Taking a ratio of these images can provide a nice measure of the local field gradient intensity, $|G|^2$.

5 OVERCOMING SUSCEPTIBILITY AND DIFFUSION

Where susceptibility and diffusive phenomena produce undesirable effects in NMR microscopy, these can be overcome, provided that sufficiently large gradients are available. For example, the use of sufficiently large read gradients in spin warp imaging can remove the distortion caused by local fields. The signal-to-noise loss which results from the need to correspondingly increase the acquisition bandwidth can be avoided¹⁷ by coadding recycled magnetization using a multiple pulse (CPMG) train. Another alternative is to use pure phase encoding since the signal may then be acquired in the absence of a read gradient under optimal bandwidth conditions.^{7,21} A further advantage of phase-encoding gradients concerns their avoidance of diffusive attenuation. The signal loss factor²¹ for a phase gradient pulse of duration t is given by $\exp(-\frac{4}{3}\pi^2 k^2 D t)$. While the smoothing effect of such k -dependent attenuation leads to blurring of sharp features in the image, the average image amplitude is determined by the height of the signal at $k = 0$ where no diffusive attenuation occurs, and hence the average image amplitude remains unattenuated. Furthermore the blurring effect may be arbitrarily reduced by using a shorter phase encode time, t . This requires a proportionate increase in phase encoding gradient amplitude, G . For resolution close to the sensitivity limit of around $10 \mu\text{m}$ pixels, and allowing for

the diffusion coefficient of water molecules, a gradient amplitude of at least 1500 mT m^{-1} (150 G cm^{-1}) is implied.

6 CONCLUSION

It is clear that both diamagnetic susceptibility and molecular self-diffusion phenomena are particularly important in NMR microscopy. Furthermore the interplay between these effects, and the applied gradients used to encode for spatial position of the spins, can lead to subtle and intriguing artifacts in the image. While these artifacts can be a nuisance, and can strongly limit the resolution available with a given imaging pulse sequence, they may be avoided altogether if sufficiently large gradients are available, without any consequent loss in image signal-to-noise ratio. It is equally clear that the effects of susceptibility and diffusion are also potentially useful in providing a signature for structure on a distance scale smaller than the pixel size. In particular susceptibility and diffusive phenomena are strongly related to the presence of heterogeneity and interfacial surfaces in the imaged sample, since both induced local fields and the inhibition of diffusive attenuation effects due to collision with surfaces arise from the presence of boundaries.

Complex Radiofrequency Pulses

Peter G. Morris

Nottingham University, UK

1 INTRODUCTION

Selective pulses were first described by Garroway, Grannell and Mansfield in 1974.¹ Their principal application is in MRI and localized MRS, where they are used in conjunction with an applied linear magnetic field gradient to isolate a slice of controlled thickness and orientation.^{2–5} They are also used, in the absence of any field gradients, as frequency, rather than spatially selective pulses, typically for suppressing signals from unwanted chemical species, for example, the lipid resonances in a high-field ¹H MRI study. Selective pulses are also gaining in importance in conventional high-resolution spectroscopy, where potential applications include solvent suppression without distortion of the frequency response (a highly undesirable feature of the binomial pulse sequences normally used for this purpose), magnetization transfer and reduction of bandwidth in two- and three-dimensional high-resolution experiments.⁶ A review dedicated to high-resolution applications is available.⁷

The basic principles of selective pulses and their design are described in the article by Maudsley (see *Selective Excitation in MRI and MR Spectroscopy*). For reasons that will shortly become apparent, selective pulses are rarely perfect and some of the consequences of their inherent imperfections are discussed in a further article by Hutchison (see *Spin Warp Method: Artifacts*). This article concentrates on the more advanced design techniques that have led to a series of sophisticated selective pulses, with properties such as self-refocusing, prefocusing or multidimensional excitation.⁸

The guiding principle for the design of selective pulses has been Fourier transform theory. On this basis, in order to achieve a slice with a square profile, the rf carrier should be modulated by the Fourier transform of a square, namely a sinc function. However, the spin system does not respond to rf pulses in a linear way, and the simple Fourier transform approach only yields acceptable results in the case of small flip angles, for which the spin system is approximately linear. How can we do better than this? Ideally, we would like to be able to define the response we need and calculate the rf envelope required to achieve it. For noninteracting spins, this amounts to being able to invert the Bloch equations. Particular solutions and a general theoretical approach to this problem based on inverse scattering theory (IST) are discussed in Section 3 of this article. However, there seems to be no completely general method for their inversion and most improvements in the performance of selective pulses have resulted from numerical optimization schemes. For example, optimal control theory has been applied by Conolly and Macovski⁹ and Lent and Kritzer¹⁰ to generate selective inversion pulses. Such gradient descent methods are prone to terminate prematurely in a local mini-

mum. Two optimization schemes, simulated annealing and a method based on a transformation to a switched reference frame known as SPINCALC, neatly avoid this problem of local minima and have enjoyed considerable success in the generation of novel pulses. These schemes, together with two novel approaches that were inspired by the natural processes of genetic evolution and the synaptic model of brain function are described in Section 4. Particular novel pulse designs are described in Sections 5–7.

2 *k*-SPACE ANALYSIS

The description of an MRI experiment in terms of its trajectory through *k* space has proven to be an excellent basis for comparing different MRI techniques.¹¹ A similar *k*-space analysis has also been applied by Pauly and colleagues¹² to rf pulse design. M_z is approximated by the equilibrium magnetization M_0 , and the solution to the Bloch equations for noninteracting spins, with the magnetization initially in the state $(0,0,M_0)$ is then:

$$M_{xy}(\mathbf{r}) = i\gamma M_0 \int_0^T B_1(t) \exp \left[-i\gamma \mathbf{r} \cdot \int_t^T \mathbf{G}(s) \, ds \right] dt \quad (1)$$

where $B_1(t)$ and $\mathbf{G}(s)$ are the rf and gradient amplitudes, respectively. This can be rewritten as:

$$M_{xy} = i\gamma M_0 \int_K p(\mathbf{k}) \exp(i\mathbf{r} \cdot \mathbf{k}) \, d\mathbf{k} \quad (2)$$

where

$$\mathbf{k}(t) = -\gamma \int_t^T \mathbf{G}(s) \, ds \quad (3)$$

It is clear from this that the transverse magnetization is just the Fourier transform of the weighted *k*-space trajectory. Theoretically, this *k*-space approach to selective pulse design is only valid in the small tip-angle limit, but in practice it works rather well even for π pulses. It also indicates very clearly the need to cover fully the appropriate region of *k* space. For two-dimensional pulses this leads to the introduction of spiral rather than the inappropriate circular paths for the gradient vector trajectories (see Section 7). Although by no means perfect, this approach at least provides a useful starting approximation for numerical optimization methods.

3 ANALYTICAL SOLUTIONS

Until recently, few analytical solutions to the Bloch equations were known, the only familiar example being the hyperbolic secant pulse,^{13,14} which is widely used where accurate selective inversion is required. Interest has grown in methods for obtaining exact general solutions. The Shinnar–Le Roux (SLR) algorithm, originally developed for generating specific m_z responses, without regard for the effects on the transverse magnetization m_{xy} ,¹⁵ has been developed to produce selective pulses of controlled phase, including self-refocusing pulses.¹⁶ It can be shown that the SLR algorithm is actually a special case of the inverse scattering algorithm.¹⁷ This method,

based on the inverse scattering transform (IST) described by Zakharov and Shabat,¹⁸ was originally developed to determine the potential giving rise to the measured scattering coefficients of a one-dimensional wave function. Several workers have shown that the problem of the inversion of the Bloch equations can be recast in this form.^{19–23} The potential is then replaced by the rf pulse envelope and the scattering matrix is simply related to the desired magnetization profile. Rourke and Morris²² have shown how to obtain general solutions, provided the desired magnetization profile is described by a rational function. They have also developed a ‘soliton lattice algorithm’, that allows the inversion problem for rational reflection coefficients to be reduced to one for zero reflection coefficient.²³ The solutions to the zero reflection coefficient problem are ‘solitons’—pulses that leave the spin system undisturbed. At first sight this does not appear to be particularly helpful. However, whereas a soliton pulse achieves nothing, it turns out that half-solitons are almost perfect refocusing pulses (both $\pi/2$ and π pulses). Furthermore, the algorithm is extremely efficient: the computation time is proportional to the number of time points defining the pulse, and for a typical pulse would usually be much less than 1 central processing unit (CPU) minute. A more general algorithm, using a conventional stereographic projection method, has been described²⁴ which does not require the magnetization response to be defined as a rational function. Although it is much less efficient than the soliton lattice algorithm, it is conceptually simple and easy to implement.

4 OPTIMIZATION METHODS

4.1 Simulated Annealing

Conventional computer optimization schemes are based on gradient descent methods in which a single error function (usually the mean square difference between the trial and target response) is minimized. They are prone to entrapment, and the multidimensional parameter space in which the pulse response is normally optimized does appear to be riddled with local minima. Clearly, this is one reason for the diversity of optimized pulse shapes in the literature. Simulated annealing^{25,26} is a widely applicable optimization technique that is effective in reaching the ‘global minimum’. Its use was first reported in the optimization of integrated circuit layouts, but its name comes from the analogy with the annealing of a metal. For annealing to be effective, the cooling must be suitably slow—if molten silicon dioxide is cooled slowly, it forms a crystalline structure, whereas, if it is cooled rapidly, it forms glass (a disordered ordered state of higher energy).

In simulated annealing, the error or cost function E is analogous to the energy of the system. The optimization proceeds by varying a degree of freedom by a small, random amount and recalculating the cost. A change resulting in a reduced cost is always accepted (as it is in conventional optimization methods). However, some changes resulting in increased cost are also accepted, with a probability that is determined by $\exp(-\Delta E/kT)$, where the parameter T can be thought of as the temperature of the system. Its choice is crucial to the success of the method. (Acceptance of a small detrimental change to

the cost function is analogous to the thermal energy which permits a structure to ‘jump out’ of a local energy minimum.) The cycle of random changes to each degree of freedom is repeated a number of times at each temperature step. As the system cools, the range of fluctuations becomes progressively more restricted. A typical simulated annealing procedure is illustrated in Figure 1, in which 20 changes are made to each degree of freedom at each temperature, and the full simulated annealing cycle is repeated three times. The cost function decreases monotonically in the first two cycles of optimization, but a small increase, representing escape from a local minimum, can be discerned near the start of the third cycle.

Although simulated annealing is conceptually simple and straightforward to implement, it can be costly in computation time, taking several hours or days to run, even on a mainframe computer. Also, its ‘random’ nature means that the same optimization, run a second time, is not guaranteed to yield the same result—unless a true global minimum is found.²⁷ Simulated annealing has proved successful in the ab initio design of a wide range of selective pulses. In particular, Ray Freeman’s group in Cambridge have generated a family of self-refocusing or BURP (band-selective uniform response prephase) pulses.^{28–30} Prefocused pulses, obtained using simulated annealing in both time³¹ and Fourier domains,⁶ have also been

Figure 1 The cost function and temperature during three cycles of optimization by simulated annealing of a prefocused $\pi/2$ selective pulse. (Reproduced by permission of Wiley from P. G. Morris, D. J. O. McIntyre, D. E. Rourke, and J. T. Nago, *NMR Biomed.*, 1989, 2, 257)

described. Simulated annealing is also useful in refining selective pulses derived by other means. An example of this is their use in the refinement of early two-dimensional selective pulses, such as the sombrero, egg carton and stalagmite pulses of Bottomley and Hardy.^{32,33} Although virtually unusable as designed, the performance of these pulses was greatly improved by optimizing rf and gradient waveforms using simulated annealing.^{27,34} As for the prefocused pulse, optimization of the Fourier coefficients of the rf and gradient waveforms resulted in smoother and more practical pulses.

4.2 Neural Networks

Neural networks are becoming increasingly important in a wide range of pattern recognition applications. In high-resolution NMR, they have been shown to be effective in analysing spectra from complex mixtures and, to a lesser degree, in classifying spectra from tissue or blood samples, for the purpose of medical diagnosis. Spectroscopists in the cancer field are most active in this area, and multicenter trials are being set up at the time of writing.

The idea of a neural network is to mimic the human brain.³⁵ The net is constructed in several layers (typically three for selective pulse design). Input, in the form of a desired excitation profile, is presented at the first layer, and the output, in the form of selective pulse amplitudes or Fourier coefficients, is taken from the last layer. The intermediate layers receive signals from the ‘neurons’ in the preceding layer, sum them with appropriate synaptic weighting, and pass the resultant signal on to the next layer. Before the neural net can be used for pulse design, it must first be trained. During the training process, excitation profiles (calculated from the Bloch equations) are presented to the net, and the synaptic weights are adjusted so that the output pulse parameters match those of the input pulse. A wide range of different types of pulse is needed if the network is to be adequately trained. This process is very time consuming, but once complete, new pulse shapes can be very rapidly determined, on presentation of the desired excitation profile at the input. Neural networks are thus attractive in situations where it is necessary to calculate selective pulses online. The practicality of the method has been demonstrated through the design of a pulse to excite antiphase magnetization ($2I_{xy}$) over a range of J values.³⁶

4.3 Genetic Methods

In genetic methods of selective pulse design,³⁷ the parameters defining the selective pulse are considered as genes. Random changes or mutations in these genes lead to a series of trial solutions, one of which is selected by the spectroscopist on the basis of some perceived desirable characteristic to be the parent of the next generation of pulses. The design does not proceed as a smooth passage through parameter space, but rather as a series of branches in ‘evolution space’. Although not widely applied to selective pulse design, genetic methods have been used to design a prefocused selective pulse³⁸ and a broadband excitation pulse with extremely uniform amplitude and phase characteristics.³⁹ Clearly one would normally set out with a particular objective in mind. However, the random nature of the mutations can throw up unforeseen novel possibilities; the broadband excitation pulse is a case in point.

4.4 SPINCALC

SPINCALC, a numerical optimization scheme introduced by Ngo and Morris^{40–42} in 1986, uses a switched rotating frame of reference to linearize effectively the Bloch equations and hence permit their inversion. In the absence of relaxation, the Bloch equation describing the magnetization $\mathbf{M}(t, q)$ of a single isochromat, labelled q , can be written as:

$$\frac{d}{dt}\mathbf{M}(t, q) = \boldsymbol{\omega}(t, q) \times \mathbf{M}(t, q) \quad (4)$$

where the instantaneous angular velocity $\boldsymbol{\omega}(t, q)$ is given by $-\gamma\mathbf{B}(t, q)$. Equation (4) can be cast in matrix form:

$$\mathbf{M}(t + \delta t, q) = \mathbf{R}[\boldsymbol{\omega}(t, q) \delta t] \mathbf{M}(t, q) \quad (5)$$

which can be ‘integrated’ to give:

$$\mathbf{M}(T, q) = \prod_0^T \mathbf{R}[\boldsymbol{\omega}(t, q) \delta t] \mathbf{M}(0, q) = \mathbf{R}_{\text{tot}}(q) \mathbf{M}(0, q) \quad (6)$$

where the total rotation matrix $\mathbf{R}_{\text{tot}}(q)$ is given by the product $\mathbf{R}_n(q) \cdots \mathbf{R}_2(q) \mathbf{R}_1(q)$, corresponding to the n discrete intervals of the pulse. The optimization proceeds by finding, for each q , a new rotation matrix that better approximates the target response:

$$\mathbf{R}_{\text{tot,new}}(q) = \delta \mathbf{R}_n(q) \mathbf{R}_n(q) \cdots \delta \mathbf{R}_1(q) \mathbf{R}_1(q) \quad (7)$$

The problem with equation (4) is a familiar one in NMR theory—the rotation matrices do not, in general, commute. The solution is similar to that adopted in the theoretical description of multipulse line-narrowing experiments, namely a transformation to a switched frame of reference:

$$\delta \mathbf{R}'_m(q) = \mathbf{U}_m(q) \delta \mathbf{R}_m(q) \mathbf{U}_m(q)^{-1} \quad (8)$$

where $\mathbf{U}_m(q) = \mathbf{R}_n(q) \mathbf{R}_{n-1}(q) \cdots \mathbf{R}_{m+1}(q)$ for $m = n - 1, n - 2, \dots, 0$, and $\mathbf{U}_m(q) = 1$ for $m = n$.

In this representation

$$\mathbf{R}_{\text{tot,new}}(q) = \delta \mathbf{R}_{\text{tot}}(q) \mathbf{R}_{\text{tot}}(q) \quad (9)$$

where $\delta \mathbf{R}_{\text{tot}}(q) = \delta \mathbf{R}'_n(q) \cdots \delta \mathbf{R}'_1(q)$. For small changes, the product of these matrices can be replaced with a sum of small vectors:

$$\delta \mathbf{R}_{\text{tot}}(q) = \sum_m \delta \mathbf{R}'_m(q) \quad (10)$$

Values of $\delta \mathbf{R}'_m(q)$ are determined for each degree of freedom (e.g. rf amplitude and phase) and a least-squares fitting procedure is used to approximate the target response. The optimization does not usually proceed directly to the final response in a single step; the corrections must be consistent with the linearity requirements and so a few intermediate targets are usually set up.

SPINCALC is extremely versatile; it can be used to design virtually any type of selective pulse, if necessary in the presence of known imperfections in, for example, the magnetic field homogeneity. Additional constraints can also be imposed at the level of the least-squares fitting, to minimise peak or mean rf power, for example.

5 ADIABATIC SELECTIVE PULSES

The hyperbolic secant is a near-perfect inversion pulse.^{13,14} It is also an adiabatic pulse; that is, it is insensitive to variations in B_1 amplitude, a feature which has been crucial to the success of the ISIS⁴³ technique for volume selection in MRS. It is not a refocusing ('pancake flip') pulse and so does not solve the problem of providing a good π pulse for multislice spin-echo imaging experiments. Refocusing does occur after each pair of hyperbolic secant pulses. However, in a multiple

echo train, significant error accumulates. This arises because the hyperbolic secant is an analytic function of infinite extent. In practice it must be curtailed, and the magnetization, instead of being perfectly spin locked, precesses around the B_1 direction.

The SPINCALC technique has been used to generate a complex adiabatic pulse of finite duration that does not give rise to cumulative errors in a multiple echo sequence⁴⁴ such as might be used for imaging in a highly inhomogeneous static field. The rf magnitudes of the optimized and the hyperbolic secant pulse are compared in Figure 2(a), and the complex

Figure 2 Adiabatic refocusing π pulse. (a) Magnitudes of optimized and hyperbolic secant (—) pulses. (b) Complex amplitudes of optimized pulse: (—) $B_{1,x}$; (---) $B_{1,y}$. amplitudes (B_{1x} , B_{1y}) of the optimized pulse are shown in Figure 2(b). The responses after four consecutive refocusing pulses are compared for optimized and hyperbolic secant pulses in Figures 2(c) and (d), respectively.

6 SELF-REFOCUSING PULSES

Slice-selective $\pi/2$ pulses, such as a truncated sinc pulse, require a negative gradient lobe to refocus the linear phase shift introduced during the course of the rf pulse. This process is time-consuming and can be a limitation when very short echo times are required—for example, in the imaging of lung tissues, or for chemical shift imaging of short T_2 species, such as the phosphate groups of adenosine triphosphate (ATP). The SPINCALC optimization procedure has been used to generate a number of phase-compensated pulses (self-refocused or pre-focused). Some of these used a selective $\pi/2$ selective π pair as an initial guess, and the optimized solution retains many of the features of its progenitor,⁴¹ whereas others were derived ab initio.⁴² As discussed in Section 3, the soliton lattice algorithm⁴³ is particularly efficient at producing refocusing pulses. An example, with an essentially perfect response, is illustrated in Figure 3.

7 MULTIDIMENSIONAL PULSES

Multidimensional pulses that localize in more than one dimension have many potential applications in MRI and MRS. For example, two-dimensional pulses can be used to limit the lateral spread of excitation from a surface coil, and a three-dimensional pulse would have obvious attractions for volume-selective spectroscopy.

k -space analysis indicates quite clearly that a uniform coverage of (multidimensional) k space is required. If the pulse is also to be inherently phase compensated then the traversal of k space must terminate at the origin. In two dimensions, the gradient trajectory that most readily meets these requirements is a (decreasing) spiral. Many choices are possible for the rf envelope. Pauly et al.¹² chose a circularly symmetric Gaussian excitation, whereas Hardy and Cline⁴⁵ have developed a variety of two-dimensional pulses which give radially symmetric excitation.

Multidimensional pulses designed on the basis of k -space analysis represent a great improvement over previous designs. However, they still display a variety of undesirable artifacts. Hardy et al.⁴⁶ have extended k -space analysis to eliminate effects due to nonuniform coverage of k space, but effects arising from the low tip angle approximation inherent in the analysis remain. These can be eliminated by numerical optimization methods, as illustrated in Figure 4, where SPINCALC has been used to optimize a radially symmetric two-dimensional π pulse.⁴⁷

There are practical limitations to the use of multidimensional pulses on standard whole body imaging systems. In particular, such systems impose severe constraints on gradient amplitudes and slew rates.⁴⁸ One way around this difficulty is to split the coverage of k -space over many pulses. In one implementation, the normal spiral gradient trajectory is replaced by spiral arms resembling a pinwheel. Although potentially

Biographical Sketch

P. G. Morris. b 1953. B.A., 1974, M.A., 1978, Cambridge; Ph.D., 1978, Nottingham. Introduced to NMR by Sir Peter Mansfield. Scientific staff, MRC Biomedical NMR Centre, London, 1980–85; Lecturer in Biochemistry, Cambridge, 1985–90; Chair of Physics, Nottingham, 1990–present. Over 150 publications in NMR, including, 'NMR Imaging in Medicine and Biology' (Oxford University Press, 1986), and, with P. Mansfield, 'NMR Imaging in Biomedicine' (Academic Press, 1982). Research interests include the development of techniques for MRI/MRS and their application to biological systems, especially the brain.

Echo-Planar Imaging

Peter Mansfield

University of Nottingham, UK

1 INTRODUCTION

Echo-planar imaging (EPI) is an extremely rapid snap-shot technique which can capture the complete data set necessary to form an image in times ranging from 20 to 150 ms. The technique was originally proposed in 1977 in a paper 'Multiplanar Image Formation using NMR Spin Echoes'.¹ In fact the multiplanar part of the technique as originally proposed has never been properly exploited, although there is now a related technique called 'echo volumar imaging' (EVI) which can, in principle, capture a volume data set in a similar time range as that indicated above.² The name EPI has evolved from the first publication and is really a shortened version of 'spin echo planar imaging.' These days, of course, people make the distinction between spin echoes and gradient echoes, but in the original version of EPI the possibility of using gradient reversals to form spin echoes and the use of 180° rf pulses to form spin echoes were both mentioned. Of course the use of rf pulses, especially at high frequencies, is a problem in medical imaging applications where rf deposition in the patient has to be limited for safety reasons.

The object of EPI then, quoting from the original paper,¹ 'is to produce, at high speed, cross-sectional NMR images corresponding to the mobile spin density variations throughout a living biological specimen. This speed is imperative if NMR is to be successfully used in medical imaging'.

2 EPI TECHNIQUE

The EPI technique is a Fourier imaging method that arose out of earlier work by Mansfield and Grannell in 1973 which was concerned with the imaging of discretely distributed systems.³ In that work NMR imaging was regarded as a special case of plane wave scattering of a pseudowave giving rise to a diffraction pattern in k -space. It was realized very early on that because of the properties of FTs, discreteness in real space and discreteness in k -space were effectively equivalent, and therefore imposing a temporal discreteness on the spin system effectively converted a continuous distribution in real space into a discontinuous distribution. Thus by exploiting these properties of k -space it was possible to encode a complete imaging plane, or indeed a whole volume of material, in an extremely short time by creating a set of suitably phase-encoded spin echoes.

3 BARRIERS TO PROGRESS—AN HISTORICAL NOTE

In the 1970s, the barriers to progress in EPI were considered to be the sheer size of gradient requirements, the speed

at which they were modulated, rapid digitization in data acquisition, and the physiological effect of fast rapidly switched gradients on the patient. Any one of these points was sufficient at that time to deter other researchers from entering the field. The combination of all the points was lethal and effectively killed the idea at birth. It was really only the determined effort of the Nottingham group to implement the technique, steadily demonstrating its applicability from initial applications in small objects and small image array sizes through to applications in pediatric imaging, again with small image array sizes, through to adult imaging that showed the way for others to try out the ideas for themselves.

4 SPECTROSCOPIC EXPLANATION OF EPI

Although we were fully aware of the k -space description of imaging³ (introducing the concept into NMR imaging in 1973), because of our concern that our ideas should be completely clear to our co-workers we chose to describe EPI in spectroscopic language so that the NMR community at large were immediately able to understand the concepts. Thus in 1984, for example,⁴ an essentially spectroscopic explanation of EPI went as follows: In EPI, the nuclear signal following slice selection with a tailored rf pulse in the field gradient G_z is encoded in frequency space by applying a trapezoidally modulated gradient G_y with period $4\tau_y$, together with a steady read gradient G_x . The timing diagram for an early EPI experiment is shown in Figure 1. The act of periodically reversing the gradient G_y is to form a series of spin echoes. That is to say, the signal response is turned into a periodic function of time with spin echos formed in both positive and negative gradient excursions. Sampling of two echo sequences with appropriate starting phases of G_y yields, after editing and splicing, a new periodic echo function with period $2\tau_y$ for echoes formed in either a wholly positive or wholly negative gradient. This generated function is Fourier-transformed to yield a discrete, periodic function of frequency (or space through the linear dependence of displacement and frequency shift caused by the gradient). The stick spectrum produced represents an enfilade view of the spin magnetization contained in the selected slice of material (Figure 2). Although the slice has a continuous spin distribution, the stick spectrum obtained makes the slice appear like a physically discrete structure. Spin magnetization is bunched into the sticks thus creating apparent gaps in the spin projection.

In order to turn the view from enfilade to oblique, the disk must be rotated slightly, so as not to cause overlap, thereby obscuring the end of each row. This is achieved in effect by applying the steady gradient G_x (see Figure 1). The sticks in the spectrum broaden to yield the oblique view (as in Figure 2). Each broadened stick represents one line in the image. The data are correctly ordered and presented to an image display device. The signal amplitude is represented as image intensity on a linear gray scale. Low signals are dark and high signals bright. The data sampling time is 32 ms. Further data manipulations and display screen update take an additional 200 ms and restrict the repetition rate to about 4 frames per second in the immediate viewing mode. Without immediate viewing, the repetition rate may be increased to 10 frames per second. Sub-

Figure 1 Pulse sequence timing diagram for EPI. Initial slice selection is performed using a tailored rf pulse B_1 (T) in a magnetic field gradient $+G_z$. For better slice definition, focused selection is used in which B_z is reversed to form the signal growth. At the signal maximum, G_z is switched off and G_x and $\pm G_y$ are switched on to create a series of spin echoes following the initial FID. The experiment is repeated with the opposite starting phase of G_y after a short delay. (Reproduced by permission of Churchill Livingstone from Mansfield⁴)

sequent viewing may be performed in a visual playback mode directly following a recorded sequence of shots.

At that time the EPI probe access was 22 cm with an object field of 19.2 cm. The imaging field was represented by a relatively crude 32×32 pixel array and the in-plane resolution was 6 mm with a selective slice thickness of 8 mm.

5 K-SPACE DESCRIPTION OF EPI

As time has passed, a number of minor variants of the EPI technique have been introduced to overcome magnet inhomogeneity effects. In the modern language of k -space scanning, the original EPI technique was essentially a half Fourier method. The modulus blipped EPI sequence⁵ is a full k -plane imaging method and, because it is a modulus technique, removes all orders of phase error in the image which may arise from local inhomogeneity effects in the specimen. In the modern vernacular⁶ EPI is described as follows. 'In EPI a different k -space sampling strategy is used. After a single spin excitation, the whole of k -space is sampled most efficiently in a single, continuous trajectory (Figure 3) by generating all the echoes as required, up to 256 in a single FID $S(t)$ (see Figure 4). Since the decay of $S(t)$ is governed by the transverse relaxation time T_2 ($T_{2,\text{brain}} = 80$ ms and $T_{2,\text{muscle}} = 50$ ms) and field inhomogeneity (in the case of gradient echoes), data acquisition needs to be completed within 50–100 ms. When this can be achieved, more complete use is made of the available spin magnetization than with conventional MRI, and the signal-to-

noise (S/N) ratio per unit time is consequently much greater,⁷ although the image is more vulnerable to distortion due to field inhomogeneity'

The echoes can either be formed as gradient echoes, as in true EPI sequences (MBEST,^{8,9} BEST,¹⁰ FLEET,¹¹ Insta-Scan,¹² spiral and square spiral EPI¹³) or as spin echoes (RARE¹⁴). The EPI pulse sequence timing diagram (Figure 4) illustrates the typical, rapidly switched, frequency-encoding gradient G_x that generates the gradient echo train $S(t)$. The rise and fall times of the gradient are of the order of 100 μs , rendering the gradient waveforms trapezoidal. The fast rise and fall times of such waveforms require low-inductance coils—100 μH in one system we have built—with low efficiency ($0.04 \text{ mT m}^{-1} \text{ A}^{-1}$), and thus put severe demands on the gradient drivers, which in that system supply up to 1000 A at 320 V. Alternatively, the waveform may be sinusoidal,¹² which requires more complicated data sampling or image processing, but allows the gradient coils to be driven as part of a resonant LC tank circuit, with considerably reduced power requirements. Phase encoding, in which the k -lines are spaced out along k_y (Figure 3), is established by pulses or 'blips' of the phase-encoding gradient G_y while the read gradient is being switched. Where high spatial resolutions are required, which are beyond the scope of the available gradients in the time available before the signal-to-noise ratio decays too far, or where images cannot be obtained which are of the desired quality, interleaved acquisitions are sometimes used. In these only sub-sets of k -space are recovered at each data acquisition, with the complete data set being assembled after several are completed. The off-setting of data in k -space which is needed

Figure 2 A sketch summarizing the main features of the EPI method. The initial selected slice of thickness Δz is produced with G_z along the direction of the static magnetic field B_0 , which also coincides with the patient axis. Modulation of G_y produces a discrete spin density profile, or stick spectrum, which corresponds to the enfilade view. Each stick comprises the signal from the shaded strip of width Δy and thickness Δz . Application of G_x broadens the sticks to give an oblique view of the spin density profile as seen between rows. (Reproduced by permission of Churchill Livingstone from Mansfield⁴)

is ensured by the use of different amplitude pre-pulses of the 'blip' gradient, and by making the 'blip' pulses such that they step the individual scans by enough lines of the final form of k -space for the interleaved scans to fill in the gaps in an ordered manner. Three-dimensional data acquisition with EPI is possible in various ways.¹⁵

The typical modular structure of EPI sequences is also shown in Figure 4. A spin-preparation module, which can be used to encode a variety of magnetic resonance (MR) parameters such as T_1 , T_2 , diffusion, and flow, and incorporates a fat-water separation module, is followed by the EPI image formation, or read-out module.¹⁶ The relative independence of the spin-preparation and imaging modules in EPI allows fast and interactive optimization of imaging parameters, such as contrast without any fundamental changes of the sequence.

Proton density, T_1 , and T_2 are the most important MR parameters for differentiation between the various organs and between normal and pathological tissue. In diseased tissue both relaxation times are often increased, but they can have opposite

Figure 3 In EPI, k -space is sampled in a single, continuous k -space trajectory within a fraction of a second. The diagram shows the starting point P. The black dots on the trajectory represent the first few points of a regular sampling pattern

effects on image contrast. In the worst case, this effect can lead to a cancellation such that pathological tissue appears normal.¹⁷ A careful separation between T_1 and T_2 contrast effects is thus necessary. This separation has not been easy in fast MRI methods such as turboFLASH, although good progress has recently been made by incorporation of a spin-preparation module.¹⁸

EPI has an inherently modular sequence structure which allows real-time changes in contrast to be introduced into images by virtue of the intrinsic NMR relaxation parameters. Comprehensive mapping of one of these NMR parameters has been demonstrated.¹⁹

In tissue, two species of proton give rise to the principal NMR signal, those in alkenic hydrocarbon chains of a fat and those of free water. Their resonance frequencies differ by 147 Hz T^{-1} because of the slightly different electronic orbital states that surround these protons, an effect known as the chemical shift. In a 100 ms echo planar image, the bandwidth separation between pixels in the blipped gradient direction is only 10 Hz (total bandwidth 160 Hz, 128×128 pixels) and thus a mis-registration of 15 pixels per tesla between images of the two species occurs. Selective eradication of the signal of either proton species in the fat-water separation module avoids this artifact and provides pure water or fat images that facilitate organ delineation'.

6 FUTURE PROSPECTS

Although EPI was conceived to tackle imaging of the body where involuntary motion is present, such as the heart and gut, with few exceptions very little work has been done in either of these areas so far. In the very recent past, more attention has been paid to the cardiac imaging, and dedicated machines for this purpose are now being supplied. These have EPI capability as a central feature in the light of the accumulating evidence

Figure 4 Diagram of a typical EPI sequence, showing the time dependence of the three orthogonal gradients G_s , G_x , and G_y , the rf pulses, and the gradient echo train $S(t)$ thus produced. The choice of axes s , x , and y is made by the operator, which allows any oblique slice to be selected if the imaging system has adequate gradient equipment. Box 1 contains optional pulses for fat or water suppression, chemical shift data, T_1 -weighting with inversion recovery, or flow encoding. Box 2 is for selective excitation. Boxes 3 and 4 show the required pulses for gradient-recalled echo (full lines) and spin echo (broken lines) EPI. The largest echo is formed at a time TE after the initial rf pulse. Optional diffusion sensitization gradients are shown in gray. The dashed line T_2 in $S(t)$ indicates the inevitable signal decay that occurs during EPI sequences; this limits the duration of the acquisition window. that it is very effective in this application.²⁰ Other areas of the body attracting increasing interest include imaging of the fetus during pregnancy. The advent of numbers of commercial machines with EPI capability will result in many more such applications being developed. In the meantime, a niche area for EPI applications which is creating worldwide interest is neurofunctional imaging of the brain. This effect manifests itself more readily at high magnetic field strengths and has been observed over the field range 1.5–4.0 T. Susceptibility changes of blood in oxy- and deoxy-hemoglobin manifest themselves as an increase in EPI image intensity of the venous blood in the oxyhemoglobin rich, as against the deoxyhemoglobin rich, state.²¹ These effects show up in localized cortical regions of the brain in response to sensory, motor, or other inputs to the brain that cause signal changes in the relevant cortical regions. This topic is rapidly expanding at the present time and seems assured of a regular position in the range of EPI applications for the study of brain neurophysiology in normal and abnormal states, and also in the study of cognitive processes in psychology and psychiatry. Another important developing role is the use of EPI for the acquisition of diffusion weighted images, particularly where it is intended to acquire the data needed to measure the diffusion tensor.²² This requires typically between six and twelve images each with different diffusion sensitization. Patient motion has been found to be a major problem in this work and EPI is a preferred data recovery method. Clinically this is of rapidly growing importance in the assessment of stroke patients for their suitability for thrombolytic therapy on admission to hospital as an emergency.²³

In all the above described applications of neurofunctional imaging considerable progress has already been made using PET, EPI, and possibly echo-volumar imaging (EVI),^{24,25}

although intrinsically less sensitive than PET, will have a role to play by virtue of the speed by which functional MR images can be obtained. At this stage, at least, MRI and PET should properly be regarded as complementary rather than competitive techniques.

The quest for higher quality EPI images combined with the greater magnetic field strengths (currently 3.0 T at Nottingham) have created a new and potentially serious problem associated with acoustic noise that is emitted during the gradient modulation process. Without suitable precautions, perceived sound levels can transcend the pain threshold and could result in permanent hearing impairment. Of course when scanning human fetuses in utero and also in veterinary applications it is not possible to use ear defenders, for example, to attenuate the noise level.

With this in mind we have recently introduced the concept of active acoustic screening in the design of high power gradient coils.^{26,27} In this approach we address the cause of the acoustic noise problem rather than treat its symptoms by balancing all Lorentz forces within the coil structure. Active acoustic screening by this means significantly attenuates the emitted noise level from the coil structure itself, thereby reducing the danger to patients of high level exposure to noise during medical MRI scans. Active acoustic screening can of course be combined with active magnetic screening, an idea introduced by Mansfield and Chapman²⁸ to combat the problem of induced currents in the structure of the static superconductive magnet when high powered gradient coils are switched within the close confines of the magnet. Reduction of sound levels will not only remove a potential danger to both operators and patients, but will also make for a more relaxed and comfortable scanning procedure.

7 CONCLUSIONS

The road to clinical EPI has been a long one lasting 20 years from its original inception. It may be argued that it was a technique ahead of its time in view of the inadequacies of magnet technology and general computing ability. However, it now seems positioned to enter its true role as the fastest method of acquisition of NMR images yet discovered with potentially very wide applications.

Image Formation Methods

Lawrence E. Crooks

Toshiba America MRI, South San Francisco, CA, USA

1 INTRODUCTION

MRI has moved from the conceptual stage in the 1970s to a multibillion dollar industry in the 1990s. Its main use today is medical diagnosis. Although this review of MRI methods centers on medical applications, MRI has potential applications in many other areas. Imaging solids is an open area that requires techniques beyond those covered here. My hope is that interested readers will use this review as a starting point for further work.

2 CONCEPTS FOR SPATIAL LOCALIZATION

Magnetic resonance images distinguish signals from distinct volume elements in an object. The basic concept underlying all techniques to achieve spatial resolution is that the resonant frequency of the nuclei is proportional to magnetic field strength. This is explicitly stated by the Larmor relationship

$$f_L = \gamma B \quad (1)$$

where γ is the magnetogyric ratio of the nuclear species and B is the magnetic field strength. So, by making the magnetic field in an object vary with position, one makes the resonant frequency of the nuclei vary with position. By knowing the position dependence of the magnetic field, the position of resonating nuclei is defined by their resonant frequency. We shall describe later the many varied ways of tailoring magnetic fields and magnetic resonance sequences to create the desired image, but will start here with an example that illustrates the concept.

Consider an object in a magnetic field that is made to vary by using what is known as a linear field gradient. In this case, the field is

$$B = B_0 + Gr \quad (2)$$

where B is the field at position r along some axis of the object, B_0 is the main field value, and G is the strength of the gradient that defines the field variation along the axis. The resonant frequency of the nuclei as a function of position along r is

$$f = \gamma B_0 + \gamma Gr \quad (3)$$

and B_0 , γ , and G are all known constants (γ is 42.58 MHz T⁻¹ for hydrogen), so position as a function of resonant frequency is

$$r = \frac{(f/\gamma) - B_0}{G} \quad (4)$$

For imaging, resonant frequency is made to correspond to position. Resonant frequency is either measured during recep-

tion or defined by the spectrum of a rf pulse excitation. During reception, frequency is measured by recording the magnetic resonance signal as a function of time and then using the frequency spectrum of the signal. Usually, a Fourier transformation analyzes the shape of the time-dependent signal and finds the strength of each of the component frequencies of the signal. The result is the relation of signal strength to frequency. Equation (4) allows the magnetic resonance frequency versus signal strength spectrum to be translated to a relationship of intensity to position.

The above equations contain a term due to the main field B_0 . By subtracting γB_0 from f one gets a new frequency centered at

$$f_0 = \gamma B_0 \quad (5)$$

This new frequency simplifies the equations and is directly available in the imager electronics. We will use this frequency in all further discussion. The simplified versions of equations (3) and (4) are

$$f = \gamma Gr \quad (6)$$

and

$$r = \frac{f}{\gamma G} \quad (7)$$

Again, these provide direct relationships between the frequency and position of the nuclei. We will next consider ways to exploit this concept for spatial localization.

2.1 Selective Irradiation

One fundamental process used in imaging and localized spectroscopy is selective irradiation. Selective irradiation uses a narrow rf range to excite only a restricted volume by matching field strength and frequency. In this case the frequency content of the rf excitation is the determining factor.

Selective irradiation for imaging¹ restricts a volume by the following sequence. First, a field gradient is applied across the object. A particular frequency now corresponds to a plane of constant frequency perpendicular to the direction of the gradient. While this gradient is present, a low-level rf pulse of relatively long duration (e.g. 10 ms) is applied to the object. The rf pulse is chosen so that its spectrum is a narrow block of frequencies (e.g. a range of 1 kHz). The region in the object whose nuclei resonate at the frequencies contained in the rf pulse will be excited, but the rest of the object is not. In this way, a planar slice through the object can be activated (Figure 1). The slice thickness and position depend on the rf pulse and on the strength of the gradient. The position of the plane can be moved by simply changing the frequency of the pulse, thereby activating nuclei at another field strength.

Consider the following example of a transaxial slice acquisition. Slice selection is performed by turning on a magnetic field gradient in the slice direction, shown along the z axis in Figure 1. A linear gradient G_z is used such that the field in the z direction has the form

Figure 1 In this example of a transaxial image acquisition, a selected plane of tissue is excited by using rf excitation that contains a narrow bandwidth of frequencies, Δf , corresponding to a section Δz along the z direction in the presence of the gradient G_z

$$B(z) = G_z z \quad (8)$$

With the z gradient on, every position along z has a different field value. So, every position has its own frequency

$$f(z) = \gamma G_z z \quad (9)$$

The rf pulse used for excitation is tailored to contain frequencies corresponding only to the Larmor frequencies of spins contained within the slice z :

$$z = \frac{f(z)}{\gamma G_z} \quad (10)$$

Only these spins will be affected and experience rotation of their magnetization vectors. These spins now have a transverse component to their magnetization and can generate signal.

The above description is accurate for small excitations, but nonlinearities in the response of the nuclei complicate the process.²⁻⁴ A number of papers provide effective solutions to the nonlinear excitation problem.⁵⁻⁷

2.2 Spectral Resolution

The next fundamental imaging process is localization of the received signal. Two approaches are available, frequency and phase encoding. Frequency encoding for projection imaging was first proposed by Lauterbur.⁸

2.2.1 Frequency Encoding

Frequency encoding uses a gradient during reception to define the readout direction, shown as x in Figure 2. The readout

gradient remains on while a signal is being recorded. The readout gradient is given by

$$B(x) = G_x x \quad (11)$$

Spins at different positions along x generate signals at different frequencies. A Fourier transform decomposes the signal into its individual frequency components. Each frequency corresponds to an x position:

$$x = \frac{f(x)}{\gamma G_x} \quad (12)$$

The strength of each frequency is related to the ‘density’ of spins in the object. This ‘density’ includes all the relaxation and other effects mentioned in the next section. We shall call this ‘density’ $\rho(\mathbf{R})$ where $\mathbf{R}$ is a three-dimensional position vector. The signal from an entire object is the sum of the signals from all the nuclei (Figure 2). Each signal includes a complex frequency and phase term for every location:

Figure 2 With frequency encoding, the collective signal from spins with different Larmor frequencies is measured and processed by a Fourier transformation to separate the individual frequency components of the input signal. By using magnetic field gradients to vary the main field spatially, frequency can be interpreted to give the location of the signal

$$\rho(\mathbf{R}) \exp(i2\pi f(\mathbf{R})t) \quad (13)$$

The total signal is thus

$$S(t) \propto \int_{-\infty}^{\infty} \rho(\mathbf{R}) \exp(i\gamma \mathbf{G}_R \cdot \mathbf{R}t) d^3R \quad (14)$$

For a two-dimensional object, a single gradient G_x projects the density of the object onto a line (Figure 3). In this case the signal is

$$S(t) \propto \int_{-\infty}^{\infty} \rho(x) \exp(i\gamma G_x x t) dx \quad (15)$$

For this signal, the above integral has a Fourier transform twin that lets us calculate the spin density projection from the recorded signal:

$$\rho(x) \propto \int_{-\infty}^{\infty} S(t) \exp(-i\gamma G_x x t) dt \quad (16)$$

These equations have infinite signal duration and possible object size. Real imaging has limited observation time and limited object size. The time limit restricts image resolution. If the signal is recorded for T seconds the Fourier integral becomes

$$\rho(x) = \int_{-T/2}^{T/2} S(t) \exp(-i\gamma G_x x t) dt \quad (17)$$

The frequency resolution is limited to $1/T$ Hz. γG_x is the frequency spread in hertz per meter, so resolution is $1/(T\gamma G_x)$ m. With discrete sampling recording a value every Δ second the maximum frequency (Nyquist) represented is $1/2\Delta$ Hz. The maximum object width is $1/(\Delta\gamma G_x)$ for complex samples. Excessively high frequencies must be rejected

Figure 3 Projection of nuclei in a plane onto a line. In the presence of a field gradient, all the nuclei along each column in the plane have the same frequency, so each frequency in the spectrum corresponds to a projection of a line of nuclei onto a single point

by filtering. These frequencies would otherwise alias and appear on top of the lower frequency parts of the image.

If two gradients are applied at the same time, their effect is like a single gradient at an intermediate angle. For example, equal x and y gradients are like a $\sqrt{2}$ stronger gradient applied at 45° between the x and y axes. This allows electronic rotation of the projection direction. This is also true for selective irradiation since it is a frequency based technique.

2.2.2 Phase Encoding

Next we consider phase encoding, which was first proposed by Kumar.⁹ In this process, gradients are used between the excitation and reception. The process is repeated with different gradient durations or strengths¹⁰ over many excitation/reception measurements. While a gradient during reception has a direct effect on the frequency of the signal, the gradient before reception affects the phase of the signal. Consider an example phase encoding gradient turned on such that the field in the y direction has a linear dependence of the form

$$B(y) = G_y y \quad (18)$$

The phase-encoding gradient is turned on for a short period of time, τ , and then removed. During this time the frequencies of the nuclei are

$$f(y) = \gamma G_y y \quad (19)$$

The phase of the nuclei at position y and time t during the gradient pulse is the integral of the frequency:

$$\phi(t) = \gamma \int_0^t G_y y dt = \gamma G_y y t \quad (20)$$

After the pulse the frequencies drop back to normal, but the accumulated phase remains constant:

$$\phi(\tau) = \gamma G_y \tau y \quad (21)$$

The repeated measurements cover a range of values of $G_y \tau$. The signal after the gradient pulse is the sum of densities with phases shifted by $\phi(\tau)$. If an infinite number of values were measured, this sum would again be an integral:

$$S(G_y \tau) \propto \int_{-\infty}^{\infty} \rho(y) \exp(i\gamma G_y \tau y) dy \quad (22)$$

For this collection of signals, the above integral has a Fourier transform twin that lets us calculate the spin density:

$$\rho(y) \propto \int_{-\infty}^{\infty} S(G_y \tau) \exp(-i\gamma G_y \tau y) d(G_y \tau) \quad (23)$$

Again, these equations have an infinite $\gamma G_y \tau$ range and possible object size. The limited number of repeated observations restricts image resolution. Object size must also be limited. For phase encoding, image resolution is determined by the range of $\gamma G_y \tau$ covered. If $\gamma G_y \tau$ ranges from $-\Gamma\pi$ through 0 to $+\Gamma\pi$, the resolution is $1/(2\Gamma\pi)$. The repeated measurements enforce discrete sampling. If N values of $\gamma G_y \tau$ are measured, the maximum object width is $N/(2\Gamma)$. For phase encoding there is no equivalent of filtering to reject signal from outside this

size range. Any signal producing object outside this range will alias and appear on top of the inner part of the image. Prevention of aliasing requires that the outer areas do not produce signal. Selective irradiations are often used to limit the signal production to the desired region only.

Unlike frequency encoding, two phase-encoding gradients applied at the same time add their effects together as if they were applied independently. This allows overlapping of different direction phase-encoding pulses, saving time in the imaging sequence.

3 IMAGE INTENSITY DEPENDENCE ON IMAGING PARAMETERS

Before further considering spatial localization, we need to determine the strength of the signal from various tissues. This is because the signal strength determines the brightness of the tissue in an image. The stronger signals give brighter tissues. Strong signals also improve the image signal-to-noise ratio (S/N). Electronic noise is included in every magnetic resonance signal, giving the final image a grainy appearance. This limits one's ability to detect image features. Thus, an improved S/N is a goal in most MRI.

The main determinants of signal strength are: nuclei density [$N(H)$ for hydrogen], the relaxation times T_1 and T_2 , and motion (cf. blood flow). Various excitation and reception parameters interact with these tissue characteristics to vary the signal intensity between tissues or between images with different parameters. Tissue motion and imaging technique response to motion is variable and will only be generally considered here. This leaves the density and relaxation times.

3.1 Relaxation Time Dependences

Three parameters that interact with the relaxation times are the pulse repetition interval TR , the echo delay time TE , and the flip angle Θ . TR is the time between successive rf excitations of a given location. The intrinsic T_1 value of the tissue determines the rate at which longitudinal magnetization recovers. By choosing TR appropriately, one can control whether a portion, or all, of that magnetization is allowed to recover. A long TR means a higher signal level but also lengthens the total imaging time. Since in most cases a heterogeneous group of tissues with a range of T_1 values will be imaged simultaneously, TR must be chosen judiciously to portray best all the tissues of interest.¹¹

TE is the time delay between the rf excitation and the measurement of the signal. Transverse magnetization created by an rf pulse begins to dephase immediately after the pulse due to T_2 and other effects such as field inhomogeneity. A 180° refocusing pulse at time $TE/2$ creates a spin echo at time TE that is corrected for field inhomogeneity effects. Without the 180° or similar refocusing pulse, the rate of signal decay will be faster, as characterized by T_2^* . A short TE will measure maximal signal early in the decay while a long TE will measure less signal later in the decay.

The flip angle is the angle through which the magnetization is rotated away from the longitudinal direction by the rf pulse. A 90° pulse will maximize the transverse component but will

also require a long recovery time before the next excitation to restore longitudinal magnetization fully. Since the recovery rate varies for different tissues depending on T_1 , a single choice of flip angle will have a different effect on each tissue. Choice of TR , TE , and flip angle will determine the image contrast and S/N as well as the total imaging time and the ability to obtain multiple sections in a single experiment.¹²

The excitation and reception schemes we consider are: (1) repeated spin echo, (2) inversion-recovery, (3) repeated limited flip angle with gradient echo, and (4) steady-state free precession. The following analysis considers that $T_2 \ll T_1$ and transverse magnetization decays completely during the repetition times of techniques (1)–(3).

In technique (1) the signal intensity of the repeated spin echo is strongly dependent on T_1 and T_2 . For single time constant relaxation and no flow, the dependence is

$$I = N(H)[1 - \exp(-TR/T_1)] \exp(-TE/T_2) \quad (24)$$

T_1 recovery limits signal strength, with long T_1 tissues being darker than short T_1 tissues.

Other excitation sequences can have a different dependence on T_1 . Technique (2), an inversion-recovery, further enhances T_1 dependence:

$$I = N(H)[1 - 2 \exp(-TI/T_1)] \exp(-TE/T_2) \quad (25)$$

assuming $TR \gg T_1$.

Here, TI is the interval between an inverting rf pulse and the 90° observing rf pulse. This technique has the highest sensitivity to T_1 . For $TI/T_1 = \ln(2)$ the signal is zero. This allows 'nulling' of the signal from one value of tissue T_1 in an image. All other T_1 valued tissues will still appear.

If the repeated excitation has a limited flip angle θ , one has technique (3). The intensity dependence using a gradient echo experiment is then

$$I = N(H) \frac{1 - \exp(-TR/T_1)}{1 - \cos \theta \exp(-TR/T_1)} \sin \theta \exp(-TE/T_2) \quad (26)$$

This allows fast imaging with a short TR . The small flip angle reduces dependence on T_1 .

If the transverse magnetization lasts longer than TR , equation (26) is no longer valid. One moves into a mode where each rf pulse creates a free induction decay (FID) and refocuses a spin echo. These two signals overlap, providing the steady-state free precession (SSFP) of technique (4). The signal dependence on relaxation times and motion is complex,¹³ but reaches a limit where

$$I = N(H) \frac{T_2}{T_1} \quad (27)$$

The brightest tissues in these images have $T_2 \approx T_1$.

4 IMAGE INTENSITY DEPENDENCE ON SIGNAL

The magnetic resonance signal is a complex valued signal. Ordinarily, it is the display of the magnitude of the signal that shows us the soft tissue anatomy. Alternatively, the phase of

the signal or the real or imaginary components of the signal can be displayed. Under ideal conditions for tissues with the same magnetic susceptibility values, the phase angle at every position in the image will be the same, and displaying phase values will be uninformative. However, field inhomogeneity, an improperly tuned imaging sequence, or disturbances such as flow can result in variations in the phase. Another cause of phase disturbance is differences in the magnetic susceptibilities of different tissues. This is seen particularly at boundaries between air and tissue or between tissue and blood. The phase image is frequently used to detect these occurrences. If desired, just the real or imaginary portion of the signal can be examined.

In most MRI data acquisitions, Fourier transformation is an essential step of digital image processing before a recognizable image is obtained. Additional levels of digital signal processing are often used such as smoothing and edge enhancement to improve the appearance of the image. The image data can be manipulated to present a different form of the data; for example, an image composed of the T_1 or T_2 values at every pixel.

5 IMAGING TECHNIQUES

Throughout the development of MRI techniques there have been many methods used for data acquisition and image reconstruction, including the sensitive point and line methods, reconstruction from projections, and Fourier imaging. A number of texts provide details about the development and historical significance of each of these.^{14–16}

MRI techniques can be classified into four types, depending on the volume that produces the received signal used to make an image: a single point, a line, a plane, or an entire three-dimensional object. Images are made of individual, resolved points, but there is a variation in when these points are defined in the imaging sequence. Single-point methods determine the points in the image most directly, by measuring points one at a time; on the other hand, three-dimensional reconstruction repeatedly measures all points simultaneously from many viewing directions or with many phase encodings and then calculates the signal contributed by each point in the object. The line and plane techniques fall between these extremes.

The basic magnetic resonance experiment starts with a sample in a magnetic field. A transmitting coil excites the spin system with an rf pulse, or pulses, causing the net magnetization vector to rotate into the transverse plane. When each pulse ceases, the spin system begins to return to equilibrium. The receiver coil is turned on, and the system acquires a FID, spin echo, gradient echo, or SSFP signal. One way to create an image would be to repeat this process for every location within the object. Such point-by-point mapping produced some of the earliest magnetic resonance images. Some point measurement techniques are also used for localized spectroscopy.^{17–19}

5.1 Single-Point Techniques

Several methods of defining sensitive points have been developed. The oldest single-point technique shapes the main magnetic field, so that the nuclei in a star-shaped region are at the resonant frequency and the nuclei outside this region are

not at the resonant frequency.²⁰ The center of the star is the sensitive point; the points of the star taper rapidly and contribute a minor amount of signal. The star shape is the point-spread function of the imager (i.e. the shape of the volume from which the signal is being received). An image is scanned by moving the object through the sensitive point. This is a very direct way to produce an image and does not require a computer for image generation. This method produced images from small animals^{20,21} and was used for human imaging by Damadian.²²

Another sensitive-point method was developed by Hinshaw.¹³ It uses alternating currents applied to three gradient coils to superimpose alternating gradients on the main field. An alternating current applied to a set of gradient coils produces an alternating magnetic field everywhere, except at the plane at the center between the coils where the field is unchanged. By applying three alternating currents of unrelated frequencies to the three perpendicular gradient coils, three mutually perpendicular planes intersect, so that only the point of intersection has an unchanging field. Areas of the object outside the point of intersection are exposed to the varying magnetic field, and the resonance signals from nuclei outside the sensitive point are frequency modulated by the variations in field. The received signal is thus a combination of the on-resonance signal from the point of intersection and the frequency modulated signals from the rest of the object. Electronic filtering removes the modulated part of the signal, leaving the signal from the point of intersection.

This intersection point can be moved by varying the currents in the gradient coils, allowing electronic scanning of the object. The point-spread function of this method is a cube with rounded edges. The signal observation technique used with the alternating gradient is the SSFP pulse sequence.¹³

Since resonance is localized to a point, most of the techniques developed for chemical NMR on isolated samples can be applied directly. Measurements of T_1 and T_2 , and $N(H)$, as well as localized chemical analysis, can be made at the selected point. Making chemical measurements at all the image points takes prohibitively long imaging times; therefore, this localized chemistry capability has usually been applied to points of interest selected from an image. In addition, if the point is positioned at a blood vessel, it is possible to acquire the signal versus time plot for pulsatile blood flow. Using gated observation, one can stop motion at a point, although nongated techniques, by averaging over the motion, usually blur movement to an average value. The single-point imaging volume limits motion artifacts to blurring because motion modifies only the intensity of the point through which something moves.

The main problem with single-point techniques is that they are slow. In the time that it takes to observe one point, all the points along a line could be observed with the same S/N. Speed would increase by the number of points in the line.

5.2 Line Techniques

Imaging speed improves considerably when all the points along a line are observed simultaneously by frequency encoding with a field gradient along the line. A Fourier transformation separates the points along the line by correlat-

ing resonant frequency with position along the line. The presence of the gradient during reception mixes chemical and spatial information. Images are made more rapidly, but they require computer processing for the Fourier transformation. Line scanning requires more complex signal excitation hardware and software than the simplest point scanners. However, they are less demanding of magnetic field and field gradient uniformity than are the reconstruction techniques to be described later.⁸ Frequency encoding collects all the points at once but requires that the signal originates only from a line volume in the object. Many different line scan techniques^{23–29} have been developed to limit the signal to a line. The techniques grew from two basic sources, Hinshaw's sensitive point, which we have just described, and Garrow's selective irradiation.¹

5.2.1 Selective Lines

When selective irradiations are used to define a line volume, a sequence of at least two irradiations with different selected directions are used. The type, order, and timing of the irradiations and signal observations determine how the line is defined and the T_1 and T_2 dependence of the signal intensity. The selective irradiation sequence we used in our work^{27,28} consisted of a 90° selective irradiation that defines a plane perpendicular to the z axis (Figure 4). Then a 180° selective irradiation inverts the nuclei in a plane perpendicular to the y axis. At a later time, a spin echo signal will arise only from the nuclei that have experienced both the 90° and 180° irradiations, that is, the line volume along the x axis that is the intersection of the two perpendicular planes (Figure 4). The line can be scanned through an object by methodically changing the frequency of either of the selective irradiations, thus exciting planes at different magnetic field strengths. The effect

Figure 4 The line of intersection of two selectively irradiated planes defines the line that produces the spin echo signal

of motion is to blur or displace individual lines. Equation (24) gives the dependence of signal intensity on $N(H)$, T_1 , and T_2 .

Other selective irradiation sequences have different dependences on T_1 . For example, Hutchison's line scan sequence²⁹ used the inversion–recovery described by equation (25). To define a line, this sequence requires the subtraction of two planar signals. The technique has a strong dependence on motion. This characteristic can be seen in a human chest image,²⁹ where the motion of the heart produced intense areas in the image outside the subject's body. One of the selective irradiation sequences developed by Mansfield²⁶ produced human images with no obvious motion artifacts.

5.2.2 Sensitive Lines

In Hinshaw's sensitive line technique,^{23,30,31} an extension of the sensitive-point technique, two alternating electric currents of the same frequency but different phases are applied to two of the gradient coils. These two varying gradient fields combine to form a rotating field gradient. Only along the axis of rotation, a linear volume, is the magnetic field constantly on resonance, so this axis is the only region of the object that is observed once all the time-dependent signal has been filtered out. Applying a constant gradient along the line allows frequency-encoded observation of the individual points along the line. The line can be scanned through an object to produce a planar image by varying the currents in the gradient coils. Because the signal is again observed as an SSFP, its intensity is given by equation (27). This technique has produced images of animals^{23,30–32} and a human head.²⁴ The effect of motion in these images is to blur or displace individual lines.

The sensitive-line techniques are more efficient than single-point techniques and are usually resistant to motion artifacts. Gating can be used to stop motion, as it can in single-point techniques. Most techniques are sensitive to blood flow.^{28,33} With selective rf pulses, blood moving within a slice has a reduced intensity. Blood moving through a slice can have increased or decreased intensity.³⁴ T_1 and T_2 can be investigated by varying timing parameters in the irradiation sequences. The presence of the gradient during the signal observation complicates the derivation of chemical information, a restriction that applies as well to planar and whole-volume techniques.

5.3 Planar Volumes

Two techniques produce images based on signals arising simultaneously from all points in a plane: projection reconstruction or zeugmatography, developed by Lauterbur,⁸ and Fourier imaging, proposed by Kumar.⁹ Zeugmatography, like X-ray computerized tomography, reconstructs a two-dimensional image from projections of a plane onto a line. Each projection is obtained by exciting all the nuclei in a plane, then frequency encoding in the presence of a linear gradient. Frequency encoding projects all the points in the plane onto a line (Figure 3). This process is repeated many times, each time with a different gradient direction, until a collection of projections is accumulated from which a computer can reconstruct a two-dimensional image of the plane (Figure 5). This process is called projection reconstruction.

Figure 5 By acquiring projections of an object using many different gradient directions, a two-dimensional image of a plane can be reconstructed

5.3.1 Projection Reconstruction Imaging

To reconstruct an image with $N \times N$ pixels requires at least $\pi/2N$ projections of $\sqrt{2N}$ points. The advantage of this technique over sensitive lines is that the signal that arises from the entire plane is a mixture of N single lines, and the electronic noise in each of the N projections is independent. The reconstruction unscrambles the N projections into N separate lines. The effect on the noise is like averaging N measurements. Thus, the final S/N of the reconstructed image is $\sqrt{\pi N/2}$ better than the S/N of a sensitive-line image.³⁵ This improvement is counteracted somewhat by 'reconstruction algorithm noise'.³⁶ Another important effect on image quality is motion artifacts. While line scans limit artifacts to individual lines, projection reconstruction distributes artifacts throughout the image.³⁷

Several human images have been generated by projection reconstruction. Lauterbur produced projection images of phantoms⁸ and, with House, of a rat by this method.³⁸ Head images have been produced by Hawkes^{39,40} using a plane through the head defined by a single alternating gradient used in the same way that the two or three alternating gradients were used by Hinshaw to define a line or a point.

5.3.2 Fourier Imaging

Like projection reconstruction techniques, two-dimensional Fourier transformation (2D FT) imaging uses frequency encoding to project the entire plane onto a line. Instead of progressively changing the direction of the line (i.e. changing the direction of the gradient across the plane), the duration or strength of a phase-encoding gradient perpendicular to the line of projection is varied to phase-encode position along the perpendicular dimension^{9,10} (Figure 6). As the strength of the perpendicular gradient increases, phase-encoding progressively increases, so that the phase encoding can be decoded using the Fourier transformation of equation (23).

Now we consider the 2D FT method that has become the standard of commercial systems today. In a typical data acquisition, position along the x direction is encoded into the frequency, and position along the y direction into the phase.

Three steps are used to localize points spatially along the three axes in space. In a two-dimensional data acquisition, the first of these is the slice selection. This is done using selective irradiations. For gradient echo imaging a z gradient is applied along with a ϕ selective rf pulse. This excites an x - y planar slice. For spin echo imaging, spatially overlapping selective 90° and 180° rf pulses are used. Additional 180° rf pulses are added if more echo images with increasing T_2 dependence are needed.^{28,41} Once a slice has been selected, phase encoding is used to provide differentiation along the y direction. Frequency encoding of the gradient echo or spin echo is used along the x direction.

Slice excitation and signal readout are repeated for N_{pe} different values of the phase-encoding gradient. Along each column, the combined signal will be increasingly distorted with each increasing phase-encoding step. As we saw in equations (22) and (23), the effect on the signal of a changing gradient over N_{pe} steps is the same as the effect of frequency encoding the signal. Figure 6 shows the effect of three increasing values of the phase-encoding gradient on the signal. Fourier transformation along the y direction gives the frequency components along y , and thus position. The two dimensions of Fourier transformation done in x and y are identical.

The acquired data are in the form of rows of sampled signals with increasing phase-encoding gradient values. Because of the unique relationship between position and precession frequency established by the field gradients, the acquired data represent the spatial frequency contributions of the image, and are called k -space data, where k is the wavenumber or value of the spatial frequency. In most human and animal images, the largest contributions to the image are made by the low spatial frequencies with decreasing contributions at higher k values. The highest k values contribute details such as edges and features of small dimension.

The three gradients of the magnet can be used interchangeably to perform slice selection, phase encoding, or signal readout. This allows images of any orientation (transaxial, sagittal, coronal, or oblique) to be defined. There are often benefits to choosing one orientation over another. It is generally desirable to orient the readout direction along the long axis of the object (for example the right-left axis through the chest in a transaxial image plane) and the phase-encoding direction along the short axis (anterior-posterior). The reason for this is that there is a time penalty incurred for increasing the number of phase-encoding cycles, but none for increasing the number of samples taken along the readout direction. Another consideration when deciding the phase-encoding direction is to align it in the direction of least motion, as it shows the greatest motion sensitivity.

In this case, to produce an image of $N \times N$ pixels, N projections of N points must be acquired. Gradients in either the main magnetic field or in the rf magnetic field used to excite the nuclei are capable of producing the phase encoding. An rf gradient is created by reversing the current direction in one half of an rf coil pair. Hoult produced a phantom object image using the rf field gradient.⁴²

Edelstein produced human images using a frequency-encoded gradient echo and a gradient of the main field for phase encoding.¹⁰ This 2D FT technique used a selective irradiation to select the plane to be imaged. We produced spin echo 2D FT images with the same type of encoding.⁴¹

Figure 6 Increasing values of the y phase-encoding gradient cause increasing distortions of the signal that is read out in the presence of an x gradient

The S/N is $\sqrt{N}$ better than the S/N of a line scan image. Its response to motion is to produce ghost-like versions of the image displaced in the phase-encoding direction.

In summary, the two planar imaging techniques just described require a computer to perform the reconstruction. The algorithms for projection reconstruction are more complex because the fast Fourier transformation, which is a standard computer algorithm, is used for 2D FT imaging. The magnetic field and field gradients have to be very uniform to produce good projections in this technique. Some distortions can be corrected by additional data processing. 2D FT images are insensitive to field variations in the phase-encoding direction. Gradient nonuniformities produce geometric distortion. Because the planar signal is measured many times, they have an S/N advantage over sensitive-point or line techniques. The larger signals associated with this advantage place greater demands on the imager because a greater dynamic range is required of the receiver. The reconstructions require signals from all points in the object, so that the value of each point depends on all the signals of the other points. Reconstructed images require a preset number of projections; therefore, the number of picture elements cannot be varied during imaging,

unlike the situation with single-point and line techniques, in which an image itself can be restricted to a specific area of interest. As in the sensitive-line techniques, the presence of a gradient complicates the determination of chemical information. Using two dimensions of phase encoding and no gradient during reception, chemical images can be made.^{43–45} These take N times longer to acquire and require three-dimensional Fourier transform processing. Gating can be applied in the same way as for selective lines.

5.3.3 Multiple Slice Imaging

So far, only single slice images have been considered. An N line image takes $N \times TR$ seconds. If one wants many slices, acquiring them one at a time is very slow. Since tissue T_2 is much less than T_1 , only a small part of TR has sufficient signal for recording. This leaves a large amount of dead time in the sequence. If the plane is defined by a selective irradiation we can use the dead time to image other slices. These multislice techniques allow the sequential selective irradiation of many planes, the signal from one plane being observed while the

other planes are returning to equilibrium.⁴¹ This is a significant increase in efficiency for clinical imaging.

For example, for a double spin echo sequence with TE values of 30 and 60 ms and a TR value of 2000 ms, allowing 100 ms to complete data readout, an interval of 1900 ms is available before the next excitation occurs. In this time 19 additional slices can be acquired by moving the slice selection to a new location that is parallel and usually contiguous to the previous slices. In this way, multislicing improves the duty cycle of the acquisition without increasing the total imaging time.

5.4 Whole-Object Imaging Techniques

It is possible to extend the simultaneous observation of the signal to all the points in an object, not just to the points in a plane. This results in the reconstruction of an entire three-dimensional object and can be done by projection reconstruction (zeugmatography), three-dimensional Fourier transformation (3D FT), or combinations of both. As far as signal acquisition is concerned, all are extensions of the two-dimensional procedures.

An alternative when using selective irradiations is to excite a thick slab rather than individual slices and use an extra dimension of phase-encoding to localize planes spatially within the slab. There is an increase in imaging time proportional to the number of phase-encoding steps used in the slice dimension. This increase is less than that associated with reconstructing the whole object.

In either case, using projection reconstruction the entire signal producing object is projected onto a line, and the direction of the line is rotated in three dimensions, so that N^3 pixels can be determined from N point projections taken over N^2 unique directions. For the 3D FT, the object is projected onto a line, and phase encoded in the two directions perpendicular to the line of projection by systematically varying the gradients in these two directions, so that N^2 projections, each with a unique phase encoding, of N points can be reconstructed into N^3 pixels. This technique is popular in low field imagers^{46–49} especially with faster limited flip angle techniques.

Because the signal arises from the entire object and is measured N^2 times, it is stronger than the signal from a single plane, and these techniques have an S/N advantage of $\sqrt{N}$ over planar imaging techniques. Of course, they take N times longer. The larger signal is even more demanding of dynamic range than planar imaging. For producing multiplanar images, they compete with two-dimensional multislice techniques. An advantage of whole-object techniques is that all pixels can have the same size, giving image slices with the same thickness as resolution. Because most other techniques are slice oriented, they have a slice thickness larger than the resolution within the plane. In projection reconstruction, when the angles of projection are all equal, the pixels are cubed elements. The computer can be used to select any view of the three-dimensional collection of pixels. 3D FT imaging easily allows different resolutions in each direction by changing gradient strengths. The image field-of-view ($N \times$ resolution) in each direction must be larger than the signal producing region or the object will alias onto itself.

The whole-object imaging techniques have increased technical requirements and enhanced performance characteristics that are direct extensions of their planar versions. The problem of storing and reconstructing N^3 pixels requires substantial com-

puter resources. Effective approaches to the reconstructions have been developed.^{50,51} Artifacts in 3D FT imaging are extensions of the ghosts of 2D FT. Lauterbur has used three-dimensional zeugmatography to produce images of human brain⁵¹ and heart.⁵²

6 IMAGE CONTRAST

Magnetic resonance image intensity dependence on imaging parameters gives MRI a powerful control of image contrast. Contrast is defined by the expression

$$C = \frac{(I_A + I_B)}{I_B} \quad (28)$$

where I_A is the feature signal and I_B is the background signal. As we saw, the magnetic resonance image intensity depends on the density distribution and the relaxation characteristics of the nuclei.

Since the water content in human soft tissue varies only by about 20%, hydrogen density $N(H)$ accounts for only a small portion of the contrast seen with MRI. Certain pathological conditions, such as edema or fluid-containing cysts, will have an increased water content and may be detectable on that basis alone.

6.1 Relaxation Time Based Contrast

Equations (24)–(27) give the image intensity dependence of tissues with various relaxation times for several imaging techniques. Figure 7 illustrates the behavior of the signal difference as a function of choice of TR and TE for tissues with different T_1 and T_2 values for technique (1) [equation

Figure 7 The effect of choice of TR and TE on the relative signal intensities I_A and I_B of tissues A and B with hydrogen density, T_1 , and T_2 values $M_{0,A}$, $T_{1,A}$, and $T_{2,A}$ for tissue A and $M_{0,B}$, $T_{1,B}$, and $T_{2,B}$ for tissue B

(24)]. Two tissues A and B have relative hydrogen density values reflected by $M_{0,A}$ and $M_{0,B}$. After a 90° rf excitation, T_1 relaxation occurs at different rates, $T_{1,A}$ and $T_{1,B}$ for the two tissues. The choice of the repetition time TR determines the relative amounts of magnetization $M_{xy,A}$ and $M_{xy,B}$ that become transverse magnetization. $M_{xy,A}$ and $M_{xy,B}$ decay with relaxation rates $T_{2,A}$ and $T_{2,B}$, respectively. The choice of the echo delay time TE will determine the relative signal intensities I_A and I_B at the time of readout. It is clear from this example that the final intensity difference is affected by both TR and TE as well as the hydrogen density, T_1 , and T_2 values of the tissues.

6.2 Vascular Contrast

All imaging sequences are sensitive to motion. Such sensitivities can be tailored to visualize blood vessels and blood flow. The contrast between vessels, blood, and surrounding tissue is based on combinations of motion, relaxation times, and spin phase. All three effects may be present in any image, but usually only two are used at a time for flow studies.

6.2.1 Relaxation and Motion Contrast

The imaging of blood often relies on the inflow of spins, which have received no previous rf excitation, into a volume of stationary tissue that is darkened by frequent rf excitation (short TR value). Inflowing blood carries full longitudinal magnetization. This gives it a bright signal compared with the suppressed background signal,^{34,53} an effect known as flow-related enhancement. In these techniques, TR and flip angle must be selected to give sufficient background suppression while allowing enough time for fresh spins to enter the volume.

These are also called time-of-flight effects. Using this mechanism, vascular contrast is generated by creating large differences in longitudinal magnetization between stationary tissue and flowing blood.

It has recently been shown that the magnetization transfer effect⁵⁴ can help to improve vascular contrast in magnetic resonance angiography.⁵⁵ Using this method, the stationary tissue signal is affected by using an off-resonance rf excitation to reduce the longitudinal magnetization of immobile protons contained in macromolecular structures of the stationary tissue. Through chemical exchange of these immobile protons with the mobile water based protons the reduced magnetization is transferred to the mobile protons. This reduces the detectable signal since signal comes mainly from mobile protons. The result is a further suppression of the stationary tissue signal without a similar suppression of the signal from flowing blood. This gives greater vascular contrast.

6.2.2 Phase Dependent Contrast

The other mechanism commonly used to generate vascular contrast exploits differences in the phase of flowing and stationary spins. This is done by using magnetic field gradients to introduce velocity-dependent phase changes. Stationary spins (zero velocity) acquire no phase angle. Moving spins acquire a phase angle that is proportional to their velocity.

When a nucleus moves through a field gradient, its frequency changes. For nuclei moving with constant velocity v along the gradient direction, their frequency is

$$f_v = \gamma G(t)vt \quad (29)$$

where $G(t)$ is the gradient as a function of time and t is time. If the gradient is on for some time Γ , the phase accumulated is the area of this function. Thus the phase Φ is

$$\phi = \gamma \int_0^\Gamma G(t)v dt \quad (30)$$

Consider a bipolar gradient waveform $G(t)$ similar to ones used for gradient echo readout. $G(t)$ is a constant pulse of $-G$ for a time τ and then reverses to $+G$ for time τ . The phase accumulated by spins moving at a constant velocity v during this gradient waveform is

$$\phi = \gamma Gv\tau^2 \quad (31)$$

For stationary spins $v = 0$, and there is no phase accumulation. All other velocities add phase to their nuclei.

When flow changes phase, if all of a sample moves at one velocity (like a plug pushed through a tube) all the nuclei have some phase change Φ . Thus, the total signal would still be strong, but will have a phase offset from zero. However, if there are many different velocities in the sample, as in laminar or turbulent flow, then each velocity will have a different phase. This distribution of phases reduces the signal and provides phase based contrast.

The distribution of phases will be centered around the phase proportional to average velocity. This allows velocity measurement. Hahn first realized that one could find the average velocity of sea water by measuring the phase of a spin echo.⁵⁶ This experiment had no spatial resolution. In MRI, the velocity dependent distribution of phase is another form of phase encoding. Here, velocity along the gradient direction is encoded rather than position. By repeating the measurement with many different values of gradient one can recover the velocity distribution.⁵⁷⁻⁵⁹ On the other hand, if the voxel is made small enough, it includes only one velocity. Then there is no destructive interference reducing the signal, and the phase gives the velocity.

7 RESOLUTION, S/N, AND IMAGING TIME

7.1 Resolution and Field of View

Image quality will be affected by its resolution, S/N, and imaging time.^{35,60} The resolution in MRI is measured by the voxel dimensions used in the image. It is determined by the frequency bandwidth of the rf excitation and reception, and the strength of the magnetic field gradients. Useful achievable resolution in a whole body image is $0.5 \times 0.5 \times 2$ mm. Despite increasing capabilities of the hardware, there are other limitations to the minimum voxel dimension. As the voxel size decreases, signal strength decreases in proportion to the reduction in the number of nuclei it contains. The S/N becomes a practical limitation. Even with improvements in noise reduction techniques, thermal motion and diffusion within a voxel may become a more fundamental constraint. Another consideration is the relationship between resolution, the size of the field-of-view (FOV) and the imaging time. For a fixed matrix size and imaging time, the FOV will be reduced in proportion to the reduction in voxel size. To

maintain the FOV at the higher resolution, additional measurements would be necessary. If they are taken in the phase-encoding direction, the imaging time increases proportionally. If the FOV is reduced, one risks the problem of aliasing.

For example, in a head image for which the FOV in the anterior-posterior direction is smaller than the size of the head, the signal from the anterior of the head that is above the FOV will appear at the bottom of the image, overlapping the posterior segment of the image. This can be overcome by eliminating signal from outside tissue using selective irradiation or presaturation.

7.2 Signal-to-Noise Ratio

The S/N is another important contributor to image quality. Parameters of the imaging sequence such as TR , TE , and flip angle will all affect the total signal. Increasing TR , decreasing TE , and using a flip angle of 90° with a long TR will all increase the total signal but may be undesirable from the standpoints of contrast and imaging time. Reduction of the voxel size provides an improvement in resolution but proportionally reduces the number of signal generating spins while noise remains the same. If more measurements are taken to provide the resolution, the extra measurements bring back some S/N. Another important determinant of signal is the frequency bandwidth of the spectrum of the voxel. Distributing the voxel signal over a larger bandwidth reduces the S/N by increasing the noise included in the image. Increasing the FOV, total bandwidth, and number of elements by the same factor has no impact on the S/N because individual voxel bandwidth does not change.

For a fixed imaging sequence, the signal intensity will also be affected by the operating frequency of the magnet. Signal increases as the square of frequency, ignoring variations in relaxation times. The noise dependence is not as easily quantified. Theory shows that at high frequency, noise increases in proportion to frequency while at low frequency it is proportional to the square root of frequency.⁶⁰ The dependence of the S/N on operating frequency has been reported experimentally to vary to the first power or less. For a well tuned system, the body itself is the biggest noise source because random currents in the body are picked up as noise by the receiver coil. The T_1 relaxation time of most tissues increases with field strength.^{61,62} Thus, the imaging parameters must change with field strength to achieve the best contrast.

7.3 Imaging Time

To acquire a full data set, excitation, and readout are repeated after TR for each point, line or projection. An $N \times N$ point scan then takes $N^2 \times TR$. Line scans, projection reconstruction, and Fourier imaging measure a line or projection every TR . Repeated measurements of the same line or projection may also be obtained in order to improve the S/N using signal averaging. In this case

$$\text{total time} = (TR)N_{\text{lines}}N_{\text{acq}} \quad (32)$$

where N_{acq} is the number of repetitions of each line or projection, and

$$S/N \propto \sqrt{N_{\text{acq}}} \quad (33)$$

Thus, improving the S/N by increasing N_{acq} requires a large increase in imaging time. For projection reconstruction and Fourier imaging the S/N also improves by

$$S/N \propto \sqrt{N_{\text{lines}}} \quad (34)$$

This efficient S/N performance is one of the main reasons for their success.

8 CONCLUSION

A number of imaging methods have been described. Early imaging development concentrated on increasing image quality in terms of the S/N, resolution, and contrast. Today, these items are sufficient for clinical medical needs and attention is moving to reducing imager cost and imaging time. Cost reduction is dominated by imager system design trade-offs. On the imaging time front, we have seen that reducing TR is one way to speed up imaging. Another is to collect multiple projections in every TR interval. Echo planar imaging^{63,64} pushes speed to the limit in this direction by acquiring all phase-encoded projections in a train of spin echoes (typically 64 echoes). By taking only some of the projections in repeated echo trains one can trade off time, the S/N, and resolution over broad ranges. This is the challenge of MRI, finding the technique and combination of parameters that best solve a given imaging problem.

Motion Artifacts: Mechanism and Control

Michael L. Wood

University of Toronto, Toronto, Ontario, Canada

1 INTRODUCTION

The acquisition of data for magnetic resonance (MR) images usually takes too long to freeze motion in the human body, such as the abdomen which moves during breathing. Motion during data acquisition blurs MR images and repetitive motion also generates ghost-like replicas of moving structures (Figure 1).^{1,2} Ghosts can mask or mimic lesions and otherwise degrade image quality. Motion also hinders the quantitative analysis of images by changing the intensity of moving anatomic structures.^{3,4}

Motion causes artifacts in MR images through several mechanisms, depending on the characteristics of motion, intensity of moving structures, and the pulse sequence, particularly the configuration of magnetic field gradient pulses. The purpose of this article is to review the mechanisms behind motion artifacts and the most successful ways to control the artifacts. The article focuses on respiratory motion in two-dimensional (2D) Fourier transform MR imaging, although the principles

apply generally to other types of motion (see *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control* and *Spin Warp Data Acquisition*). Some of the principles also apply to imaging techniques, such as echo planar imaging, spiral scanning, line scanning, and fast spin echo imaging, but specific reports should be consulted for more detail.⁵⁻⁸ (See also *Echo-Planar Imaging; Image Formation Methods; Projection-Reconstruction in MRI; Spiral Scanning Imaging Techniques*.)

2 RESPIRATORY MOTION

Various physiologic motions and body movements degrade MR images. The most problematic physiologic motions include blood flow, cerebrospinal fluid (CSF) pulsation, respiratory motion, cardiac motion, and gastrointestinal peristalsis. Blood flow can cause intense ghosts and inconsistent image intensity within vessels, which can mimic dissections and thrombi or mask pathology (see *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control*). Body movements, such as nodding of the head or shifting of position, are encountered frequently during MR imaging of uncomfortable or disoriented patients and infants and children. Breathing is the main problem for abdominal MRI, causing the liver, spleen, pancreas, and kidneys to move craniocaudally and anteroposteriorly (see *Abdominal MRI*). The amplitude, period, and pattern of respiratory motion vary considerably between individuals. Furthermore, various diseases of the heart or lungs result in abnormal and exaggerated breathing (see *Lung and Mediastinum MRI*). Nevertheless, certain trends are recognized.

In the upper abdomen, the most displacement tends to occur craniocaudally, averaging about 20 mm, but approaching 100 mm during deep breathing.⁹⁻¹¹ In the transverse plane, the displacement of the abdominal wall generally is only about one-sixth that of the longitudinal displacement of the abdominal contents.⁹ The thorax, through the action of the intercostal muscles, can experience substantial displacement in the transverse plane. Motion of the diaphragm during breathing also tends to flare the base of the rib cage.

3 MODULATION OF k -SPACE

Data from Fourier imaging correspond to the coordinates k_x and k_y of k -space, which are associated with frequency encoding and phase encoding, respectively (see *Image Formation Methods* and *Spin Warp Data Acquisition*). Images are obtained simply by inverse Fourier transforming the k -space data. Each row of k -space has a distinct value of k_y , depending on the phase-encoding gradient pulse. Typically, 256 values of k_y are acquired to produce 256 pixels in the phase-encoding direction. As illustrated in Figure 2, there is a much longer time between consecutive k_y values than between consecutive k_x .

Ghosts arise when motion causes a periodic modulation of the magnetization measured as data for an MR image.¹²⁻¹⁵ Motion affects the magnitude or the phase of the magnetization, which disrupts the Fourier transform relationship between k -space and image. Respiratory motion tends to modulate k -space periodically or at least quasiperiodically. The inverse

Figure 1 Ghosts and blurring caused by respiratory motion and also blood flow during 2D MR imaging of a normal patient: (a) and (b) are slices in the transverse and coronal orientations, respectively, acquired during normal breathing on a commercial 1.5 T MRI system using a spin echo pulse sequence with TR/TE (repetition time/echo time) = 300/12 ms, slice thickness = 10 mm, field-of-view (FOV) = 350 mm, and data matrix = 256×256 . The same patient held his breath during the acquisition of (c) and (d), each of which required 13 s using a spoiled gradient echo pulse sequence with $TR/TE = 50/4$ ms, rf tip angle = 60° , inferior and superior spatial presaturation, and otherwise identical imaging conditions

Figure 2 Ghosts along phase-encoding direction of Fourier MR images, due to much longer time between consecutive values of k_y than k_x . Typical 2D Fourier pulse sequences fill k -space row by row where each row has a distinct k_y , corresponding to a phase-encoding gradient pulse of different amplitude. Sample a is the first sample in the echo after the strongest phase-encoding gradient pulse. Sample b follows approximately $10 \mu\text{s}$ later. The echo reaches its peak at $k_x = 0$ and the last sample from this first echo is stored at position c. The time between samples a and c is the sampling time, which is typically about 10 ms. The next row is filled with samples from the next echo, for which the amplitude of the phase-encoding gradient is reduced slightly. The time between samples a and d is the repetition time, TR , which typically is on the order of 1 s

Fourier transform of the function describing the modulation is a series of peaks corresponding to harmonics in the modulation function. These peaks can be characterized by a point spread function (PSF).² Inverse Fourier transforming the k -space data yields an image with ghosts, which are the average magnetization convolved with the peaks associated with modulation.

Respiratory motion is not rapid enough to modulate the data for different k_x and the same k_y . When TR is on the order of 1 s, respiratory motion can modulate the k_y direction, thereby producing ghosts along the phase-encoding direction of an MR image. Incidentally, 3D MR images have two phase-encoding directions and ghosts propagate along both.²

The phase-encoding direction can be chosen to redirect ghosts—but not to eliminate them, because motion in any direction causes artifacts in MR images.¹² The anteroposterior direction in Figure 1(a) was resolved by phase encoding. Ghosts from blood flow through the aorta interfere with the left lobe of the liver. If the left–right direction had been phase encoded instead, the column of ghosts from the aorta would have been rotated 90° and these ghosts would have interfered with the right lobe of the liver. Thus, the phase-encoding direction influences the overlap of ghosts with other structures. The preferred choice depends on the anatomic site and the slice orientation.

4 MOTION-INDUCED PHASE SHIFTS DURING TE

4.1 Mechanism

Movement during the application of gradient pulses used for spatial encoding can affect the phase of the magnetization

adversely. The phase, $\phi(TE)$, that accumulates after a radiofrequency (rf) pulse at time $t = 0$ until the center of an echo at time TE is particularly relevant to spatial encoding and is given by the following equation:

$$\phi(TE) = \gamma \int_0^{TE} \mathbf{r}(t) \cdot \mathbf{G}(t) dt \quad (1)$$

where γ is the gyromagnetic ratio and $\mathbf{r}(t)$ and $\mathbf{G}(t)$ are time-dependent vectors representing the position of the spins and the three gradient waveforms, respectively.

4.1.1 Gradient Moments

The configuration of gradient pulses and the position of the spins need to be known to calculate $\phi(TE)$. It is simplest to consider one direction at a time, because motion along each direction contributes separately to $\phi(TE)$. Let $r(t)$ denote the component of $\mathbf{r}(t)$ along a particular direction of interest. Since TE is usually brief relative to movements in the body, it is useful to expand $r(t)$ in the following Taylor series:

$$r(t) = r_0 + v_0 t + \frac{1}{2} a_0 t^2 + \dots \quad (2)$$

The symbols r_0 , v_0 , and a_0 represent the position, velocity, and acceleration, respectively, at time $t = 0$. This Taylor series expansion is useful when only two or three terms are significant. After substituting equation (2) into equation (1), $\phi(TE)$ becomes the following:

$$\begin{aligned} \phi(TE) = \gamma \left[r_0 \int_0^{TE} G(t) dt + v_0 \int_0^{TE} t G(t) dt + (1/2) a_0 \right. \\ \left. \times \int_0^{TE} t^2 G(t) dt + \dots \right] \quad (3) \end{aligned}$$

The integrals in equation (3) are defined as the zeroth, first, and second moments of the gradient waveform, $G(t)$. Normally, the slice selection and frequency-encoding gradient waveforms are configured so that $\phi(TE)$ vanishes. Two identical pulses in a gradient waveform contribute equally to the zeroth moment, but the later pulse influences higher order moments more. If a gradient waveform has a large first moment, equation (3) indicates that a given velocity will contribute more to $\phi(TE)$. Assuming that the time between the two pulses in Figure 3 is negligible, motion of constant velocity, v , along this direction would make $\phi(TE)$ nonzero by $\frac{1}{2} \gamma G v TE^2$, which is a motion-induced phase shift. Larger phase shifts occur for faster motion or longer TE . Similarly, acceleration influences $\phi(TE)$ in proportion to the second moment. Thus, gradient moments characterize the sensitivity of a gradient waveform to motion.

Phase shifts induced by motion during TE present three problems for MR images—ghosts, intravoxel phase dispersion, and spatial misregistration. Ghosts arise if the velocity changes during different TE intervals, which is usually the case. Intravoxel phase dispersion, which arises when a distribution of velocities exists within a voxel, weakens the net magnetization within the voxel. Misregistration of flowing blood within a vessel can occur when the vessel courses obliquely within a slice, because frequency encoding and phase encoding are separated by a few milliseconds.¹⁶

Figure 3 Phase shift at time TE , as a result of motion during application of gradient pulses. The phase of the magnetization from a stationary structure and one moving at constant velocity along the frequency-encoding direction are shown for a two pulse gradient waveform, such as that used for frequency encoding in a gradient echo pulse sequence. The gradient waveform is designed to yield an echo midway through the second pulse, at which time, TE , the cumulative time integral or area vanishes. Motion makes the magnetization phase at TE nonzero, because the phase accumulates at a position-dependent rate

4.2 Control

4.2.1 Gradient Moment Nulling

Motion-induced phase shifts can be reduced by configuring a gradient waveform to make its first and possibly higher moments vanish at the time TE .^{17–19} (see also *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control*). This procedure

Figure 4 Demonstration of GMN in reducing ghosts in 1.0 T abdominal MR image. First-order GMN in both the slice selection and frequency-encoding directions was used for the right-hand image, but not the left-hand image. All other imaging conditions were the same for both images, including $TR/TE = 2000/45$ ms. The phase-encoding direction was anteroposterior. Note the bright blood vessels in the liver in the left-hand image. (Reproduced by permission of the American Institute of Physics from M. L. Wood and Q. S. Xiang, in 'Medical Physics Monograph No. 21: The Physics of MRI: 1992 AAPM Summer School Proceedings', eds. M. J. Bronskill and P. Sprawls, 1993, p. 383)

cedure is called gradient moment nulling (GMN), motion artifact suppression technique (MAST), flow compensation, gradient motion rephasing (GMR), gradient moment compensation (GMC), and other names.²⁰ According to equation (3), first-order nulling, in which the first moment of a gradient waveform becomes zero, prevents motion of constant velocity from time $t = 0$ to TE from shifting the magnetization phase. In implementing GMN, usually another pulse needs to be added to the gradient waveform. Seldom are gradient moments higher than the first nulled. Usually, GMN is applied to the frequency-encoding and slice selection gradient waveforms. Occasionally, GMN is incorporated into the phase encoding gradient waveform to eliminate oblique-flow artifacts.

Attributes of GMN include a sometimes dramatic reduction of ghosts and a return of the image intensity to the expected level, as illustrated in Figure 4. Once GMN has been implemented into a pulse sequence, its use is simple and it does not prolong patient preparation or data acquisition. It applies to all types of motion and all pulse sequences. Unfortunately, the extra gradient pulses required by GMN prolong the minimum TE that can be achieved. This is a serious limitation for essentially every pulse sequence. Moreover, hepatic blood vessels made bright by GMN might be mistaken for pathology on long TR /long TE images.

5 INTENSITY OF MOVING STRUCTURES

5.1 Mechanism

When structures that move are more intense, their ghosts are correspondingly more intense. The intensity of any ghost is proportional to the intensity of the moving anatomic structure that created it. The intensity of a particular structure relative to the background noise depends on the pulse sequence and its parameters, such as TR and TE , and general conditions, such as the signal-to-noise ratio (S/N), which depend on other factors, such as the magnetic field strength and receiver coil sensitivity. For example, adipose tissue in short TR /short TE spin echo pulse sequences tends to be the most intense structure, in which case the transverse movement of the abdominal wall during breathing creates conspicuous ghosts. Blood flowing through single slice, gradient echo images usually is much more intense than in spin echo images, in which case the ghosts are also more intense. High-field images tend to have conspicuous ghosts, principally because these images have less random noise to hide ghosts and also greater contrast between adipose tissue and other tissues.^{12,13} Positioning a surface coil near a moving structure can also cause ghosts to be more intense than if a coil with lower sensitivity had been used.

5.2 Control

Reducing the intensity of a moving structure reduces the intensity of the associated ghosts. Such an action is acceptable only if the structure need not be imaged. Several methods for reducing the intensity of certain anatomic structures have been advanced, including spatial presaturation, spectral presaturation, short T_1 inversion recovery (STIR), and surface-coil imaging. Each is explained below, beginning with spatial presaturation, which is the most widely used.

5.2.1 Spatial Presaturation

A few milliseconds before each rf excitation, one or more spatially selective rf pulses can be applied to tip longitudinal magnetization in a designated region into transverse magnetization.^{12,19} Ideally, this so-called spatial presaturation would leave no longitudinal magnetization in the region for an rf excitation pulse to tip into transverse magnetization and thereby elicit an MR signal. Spatial presaturation can affect a strip in any orientation. Presaturation seems to be implemented on every commercial MRI system and identified by many different acronyms, including SAT, REST, PRE-SAT, PRESAT, BFAST, and SATURATION.²⁰

Spatial presaturation is compatible with essentially every pulse sequence and generally does not prolong data acquisition or require any special preparations. However, presaturation increases the time to prepare each MR signal, such that fewer slices can be imaged during the same TR . The rf pulses required by presaturation also increase the power deposited during data acquisition. These disadvantages of presaturation are usually tolerable given its attributes.

There are many useful applications of presaturation, one of which is to reduce the intensity of the abdomen in images of the spine, so that ghosts from abdominal motion cause less interference. Ghosts caused by the pulsatile flow of blood through a slice can be reduced by presaturating regions on both sides of the slice, as illustrated in Figure 1. Incidentally, presaturation can also restrict the field-of-view (FOV) and help distinguish between arteries and veins (see *Time-of-Flight Method of MRA*).

5.2.2 Spectral Presaturation

The objective of spectral presaturation is to reduce the intensity of either fat or water, based on their characteristically different Larmor frequency. At 1.5 tesla (T), the Larmor frequency of water is about 225 Hz greater than the Larmor frequency of fat. Spectral presaturation is similar to spatial presaturation, except that the rf pulse is spectrally selective rather than spatially selective. The rf pulse for presaturating fat at 1.5 T would have a frequency about 225 Hz less than the rf pulse for generating an MR signal from water. Spectral presaturation is implemented on many commercial MRI systems and identified by acronyms, including FATSAT, SPIR, and ChemSat.²⁰ The attributes and limitations of spectral presaturation are similar to those of spatial presaturation, but an additional limitation is that spectral presaturation requires a homogeneous magnetic field. The field can be made more homogeneous through shimming, although shimming takes time.

5.2.3 STIR

Short T_1 inversion recovery (STIR)²¹ is an inversion–recovery pulse sequence in which the inversion time is chosen such that longitudinal magnetization from adipose tissue reaches zero when each rf excitation pulse is applied. The short T_1 of adipose tissue allows STIR to zero its image intensity and still achieve good contrast between other tissues. Unfortunately, STIR gives fluids a high intensity and their motion can generate more conspicuous ghosts. The concept of selecting the inversion time to null a tissue with a characteristic T_1 applies also to tissues other than adipose.

5.2.4 Surface-Coil Imaging

The sensitivity of surface coils decreases with distance from the coil (see *Surface and Other Local Coils for In Vivo Studies*). Although this compromises image uniformity, it is beneficial when the lowest sensitivity is near a moving anatomic structure that does not need to be imaged. For example, the spine coil used for most spine images makes the intensity of the anterior region of the abdominal wall much less than that of the posterior region close to the coil. Consequently, ghosts from movement in the anterior region are much less intense than in images acquired using the body coil.

6 DISPLACEMENT DURING TR

6.1 Mechanism

The amount of movement during data acquisition affects the intensity of ghosts. Greater displacement (pixels rather than centimeters) causes more modulation of the k -space data. When the displacement is more extensive, ghosts located farther from moving structures tend to become more intense.¹²

6.2 Control

Displacement during TR can be controlled by several methods, including restraining, breath-holding, gating, triggering, retrospective gating, and postprocessing, each of which is outlined below.

6.2.1 Restraining

Restraining could be considered insurance against extensive displacement. Restraining applies to a wide variety of MRI examinations, although the exact procedure depends on the anatomic site, resourcefulness of the operator, and cooperation of the patient. The anterior–posterior movement of the abdomen can be restricted using an inflexible band wrapped around the abdomen. However, a tight band might lead to an altered pattern of breathing with more displacement in the craniocaudal direction, which would be counterproductive.

6.2.2 Breath Holding

Images acquired rapidly can sometimes capture anatomic structures while they are essentially stationary (see *Echo-Planar Imaging; Spiral Scanning Imaging Techniques* and *Whole Body Magnetic Resonance: Fast Low-Angle Acquisition Methods*). Respiratory motion was frozen during the 13-s data acquisition for Figures 1(c) and (d). However, the left lobe of the liver seemed to be affected by heart motion transmitted through the diaphragm. Misregistration of anatomy is a problem in images acquired during repeated breath holding periods. Although techniques for producing MR images rapidly continue to improve, they still provide less contrast and S/N than more time-consuming techniques. Certain rapid imaging techniques are prone to degradation caused by abrupt changes in magnetic susceptibility, chemical shift, and other resonance offsets. Nevertheless, further technical developments are anticipated.

6.2.3 Gating

The principle behind gating is to allow data acquisition to proceed only if the displacement does not exceed a predetermined limit.^{22,23} Otherwise, data are rejected and data acquisition is repeated until the displacement becomes acceptable. By rejecting data acquired during extreme displacements, gating reduces ghosts and blurring and makes it appear as if less motion actually occurred. Gating has been applied to overcome respiratory motion for MR imaging of the abdomen and thorax, although now it is rarely used.

The most significant limitation of gating is that it requires data acquisition to be repeated, which typically doubles or triples the data acquisition time. Data acquisition need not take as long if only the most extreme displacements are rejected or if gating is used for only a fraction of data acquisition.²⁴ Another limitation is that gating relies on measurements of displacement, typically provided by a transducer, although MR signals can also be used to monitor position.²⁵ The use of a transducer prolongs patient preparation and also adds complexity to the procedure.

6.2.4 Triggering

Data acquisition can be triggered to a specific phase of a repetitive motion.¹² Triggering has been used effectively for imaging of the heart, blood vessels, and the spine, in which the pulsatile flow of CSF causes ghosts (see *Cardiac Gating Practice* and *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control*). These movements are periodic and correlated with the electrocardiogram (ECG) or a peripheral pulse, which can be monitored and used as the data acquisition trigger. Data for separate images can be acquired at different delays after the trigger is detected. Triggering reduces ghosts and blurring, to the extent that the data for each image are acquired at the same phase of a periodic motion. If the trigger is irregular, TR varies, which in itself causes ghosts.^{23,24} Irregular triggers and the lack of a convenient physiologic trigger limit the usefulness of triggering at controlling respiratory motion.

6.2.5 Retrospective Gating

Retrospective gating monitors a signal correlated to motion and uses it later to sort the data measurements into groups acquired approximately at the same time relative to this signal.²⁶ (See also *Cardiac Gating Practice*.) The time that each echo is measured relative to the trigger is recorded with the data. After the data have been acquired, they are sorted so that separate images can be reconstructed from data acquired at similar stages of motion. Cardiac imaging is the best known application of retrospective gating, but it could be extended to control respiratory motion.

6.2.6 Postprocessing

Data that have already been collected can be processed to undo the degradation caused by motion.²⁷ A realistic model of the motion is needed for effective postprocessing. Several strategies for extracting information about motion during data acquisition have been explored, including the use of navigator echoes interleaved with the echoes intended for imaging.²⁸ One important attribute is that postprocessing can reduce both the ghosts and blurring caused by motion. Postprocessing is diffi-

cult for respiratory motion because the associated displacement varies within the abdomen.^{29,30}

7 PERIODICITY OF MOTION

7.1 Mechanism

Repetitive motion, such as respiratory motion, causes ghosts in MR images. Although respiratory motion has a range of frequencies, often one frequency dominates. Usually, the phase-encoding gradient is incremented monotonically, in which case single frequency motion yields a pattern of regularly spaced ghosts, with the separation, Δy , given below:²

$$\frac{\Delta y}{FOV} = F \cdot NSA \cdot TR \quad (4)$$

where FOV is the field-of-view, NSA is the number of data measurements averaged, TR is the repetition time, and F is the frequency of motion. The product of NSA and TR is the time after which the amplitude of the phase-encoding gradient is changed. Ghosts that would extend beyond the FOV are folded back into MR images from the opposite side, as a result of aliasing.

7.2 Control

Methods to control the periodicity of motion include averaging, pseudogating, ordered phase encoding, and ghost interference. Each of the remedies are explained below, beginning with averaging, because it is the most versatile and widely used.

7.2.1 Averaging

Multiple sets of data can be averaged. The number of repetitions is called the number of signal averages (NSA) or acquisitions, data sets, averages, excitations, repetitions, projections, views, and profiles.²⁰ Averaging reduces random noise in MR images and it can also reduce ghosts if the motion is in a different phase when repeated data are acquired. The pattern of ghosts that would arise from separate reconstruction of these data would be similar, except for the phase of each ghost.²⁴ Averaging the data, or equivalently, images, allows cancellation of ghosts that have different phase.

Two alternative strategies for collecting repeated data are known as parallel and serial averaging.³¹ In parallel averaging, data for each particular k_y are repeated before collecting data for a new k_y . Serial averaging collects complete sets of k -space serially. Equation (4) applies explicitly to parallel averaging. The factor NSA does not affect the separation of ghosts in serial averaging. Serial averaging is advantageous for reducing ghosts because it provides a much longer time between repeated data, so that a moving structure is more likely to be in a new position for the repeated data.

Averaging is easy to use, versatile, and reasonably effective at suppressing ghosts. However, averaging prolongs data acquisition by the factor NSA , making it more practical for shorter TR . Attempts at making averaging less time-consuming have been proposed, such as repeating only part of the data. It is difficult to suppress ghosts completely by averaging, because the intensity of ghosts generally decreases only as $\sqrt{(NSA)}$.³² Data

acquisition would need to become four-times longer to reduce ghosts in one-half. Moreover, averaging fails to reduce the blurring caused by repetitive motion. In spite of these limitations, averaging is a useful remedy for motion artifacts, because of its simplicity and versatility.

7.2.2 Pseudogating

Pseudogating uses aliasing to superimpose all of the ghosts back on the moving structure or at a distance of one-half of the FOV from the moving structure. A deliberate attempt at pseudogating consists of choosing NSA and TR so that $\Delta y = n \cdot \text{FOV}/2$, where n is a positive integer.^{24,33} Pseudogating is not widely used to control respiratory motion, because it is difficult to choose the proper TR and NSA and the choice tends to require a long data acquisition time.

7.2.3 Ordered Phase Encoding

Ordered phase encoding (OPE) alters the sequence in which data for different k_y are acquired, depending on the position of a patient.^{29,34,35} Ordered phase encoding is referred to as ROPE, COPE, POPE, respiratory compensation (RESCOMP), respiratory-sorted phase encoding (RSPE), phase-encoded artifact reduction (PEAR), phase reordering, and FREEZE.²⁰ Prior to the start of data acquisition, OPE requires information about the pattern of motion, which is usually provided by a transducer attached to the patient. Prior to each rf excitation, the position is measured to choose the particular value of k_y to acquire. In practice, end expiration, end inspiration, and positions in between these two extremes are assigned blocks of k -space (see Figure 5).

If successful, OPE makes it appear as if a patient simply inhaled once during data acquisition, even though many cycles of respiratory motion occurred. The resulting images should be free of ghosts, because the motion modulates the data monotonically,

Figure 5 Mechanism of ordered phase encoding. The curve represents the position of the chest during breathing and the points demarcate times when data for a few values of k_y are sampled. These repetitive displacements become monotonic in k_y if the k_y are acquired in the order indicated. (Reproduced by permission of the American Institute of Physics from M. L. Wood and Q. S. Xiang, in 'Medical Physics Monograph No. 21: The Physics of MRI: 1992 AAPM Summer School Proceedings', eds. M. J. Bronskill and P. Sprawls, 1993, p. 383)

rather than periodically. Unlike gating, OPE does not interrupt data acquisition, so it should not prolong data acquisition. However, OPE is technically difficult to implement and requires special patient preparation. Consequently, the success of OPE relies on the cooperativeness of the patient and the expertise of the MRI operator. Ordered phase encoding applies to a specific movement, usually respiratory motion. It does not generally reduce ghosts from other movements simultaneously and it fails to decrease the blurring caused by movement.

7.2.4 Ghost Interference

A complex-valued image with ghosts can be decomposed into a ghost mask superimposed on an ideal image representing the time-averaged magnetization. Unlike the ideal image, the phase of the ghost mask depends on the phase of the periodic motion. Consequently, data for two or three images can be acquired interleaved and with the order of the phase-encoding steps shifted.³⁶ These data are modulated by motion differing only in phase, so the associated images have a similar pattern of ghosts but with different phase. Images from the data can be combined to generate a ghost-free image. This ghost-interference method is simple, because it does not need patient monitoring or detailed knowledge of the motion. Ghosts cancel, provided that the motion is at least quasiperiodic. The primary drawbacks are a doubling or tripling of the data acquisition time and the assumption of quasiperiodic motion.

8 SUMMARY

Respiratory motion remains troublesome for MRI in spite of a decade of research directed at understanding and controlling the associated artifacts. Respiratory motion is repetitive, so it generates blurring and ghosts in MR images. Blurring is undesirable because it degrades spatial resolution and contrast by spreading structures over a broader range of pixels than warranted. The ghosts are distributed along the phase-encoding direction of MR images, regardless of the direction of motion. Ghosts in MR images are undesirable because they can mask pathology or mimic it.

Many methods to control respiratory motion artifacts have been advanced, although none are always completely effective. Some methods, such as spatial presaturation, reduce the intensity of ghosts by reducing the intensity of moving anatomic structures. Other methods reduce the displacement during data acquisition or exploit the periodicity of respiratory motion. All of the methods reduce ghosts and some of them also decrease blurring. Methods that do not prolong data acquisition or patient preparation are also desirable. Every one of the methods has a deficiency, but fortunately they are not the same. Most of the methods to control motion artifacts are not mutually exclusive so they can be combined for greater artifact suppression. The best combination is debatable, but it probably depends on the anatomic region, pulse sequence, and MRI system.

Multi Echo Acquisition Techniques Using Inverting Radiofrequency Pulses in MRI

Jürgen K. Hennig

Universität Freiburg, Germany

1 INTRODUCTION

Fast multi echo acquisition techniques comprise a family of MRI sequences, which are meant to reduce the total acquisition time of an MRI examination (see *Echo-Planar Imaging* and *Whole Body Magnetic Resonance: Fast Low-Angle Acquisition Methods*). By sampling more than one line of k -space per excitation of the spin system, the saturation effects of multi-excitation techniques are avoided. In conventional techniques, one line of k -space is sampled per excitation of the spin system. For imaging of protons in living tissues repetition times of the order of 500 ms or more are required between successive excitations in order to avoid saturation of spins. Although images from several different sections of the body can be acquired in one such data collection period by means of multi-slice acquisition, and although images of different contrast can be obtained using multi echo techniques, the resulting acquisition times are in the region of several minutes, which is rather long compared with physiological timescales. Motion due to cardiac action, respiration and peristalsis will lead to artifacts; involuntary motion is a severe problem in uncooperative patients such as small children. This and the high cost of MRI equipment has led to intensive research into faster imaging techniques.

The possibility of scanning more than one line of k -space after a single excitation has been proposed by Mansfield in his paper on echo planar imaging¹ (see *Echo-Planar Imaging*). The technological problem with the proposed method is that the timescale for scanning k -space by gradient reversal is given by the field inhomogeneity dependent signal decay time T_2^* , which for in vivo applications typically lies in the range 20–50 ms. To sample 256×256 data points on such a timescale requires extremely strong and fast gradients, which only recently have become available outside of research laboratories (see *Gradient Coil Systems*). An additional problem is the high bandwidth that has to be used for fast data sampling, which results in a considerable decrease in the signal-to-noise ratio. Finally, it should be mentioned that the physiological thresholds for nerve stimulation by fast gradient switching do allow reasonably fast acquisition times of medium resolution images (60 ms for a 128×128 image matrix). However, it is questionable whether high resolution imaging with matrices of 256×256 or 512×512 with the same or even lower acquisition times would be tolerable, even if it were technically feasible.

Mansfield mentioned in his original paper¹ the possibility of supplementing refocusing by gradient inversion by rf refocus-

ing using 180° pulses. Although this is an intrinsically slower procedure, because gradient switching is faster than the application of a refocusing pulse under in vivo conditions, it has the intrinsic advantage that the signal decay of spin echoes is given by the relaxation time T_2 , which is considerably longer than the field inhomogeneity dependent time T_2^* . An additional benefit of rf refocusing is the fact that spin echoes are self-compensating for a large number of imperfections arising from susceptibility effects (see *Susceptibility Effects in Whole Body Experiments*), dephasing due to chemical shift, motion (see *Motion Artifacts: Mechanism and Control*), etc. Imaging techniques based on spin echo formation are therefore intrinsically more stable and reproducible under the nonperfect conditions of a clinical examination, which is of considerable interest for the radiologist, who has to base a diagnosis on the resulting images.

In spite of these apparent advantages of spin echo refocusing, it was several years before a practical MRI experiment was done using this concept. The problems in implementing the apparently simple concept are discussed in Section 2. After the first demonstration of the rapid acquisition with relaxation enhancement (RARE) experiment,² it was another 5–6 years before a routine whole body system finally met the strict requirements of the sequence regarding the temporal stability against eddy current effects induced by the switched gradient fields.

After the proliferation of the use of the sequence, under various acronyms (FAISE, FSE, TSE, etc.), on routine whole body scanners, RARE made a tremendous impact on the way in which a routine diagnostic examination was performed. Previously, conventional spin echo sequences with short recovery times of around 500 ms had been the basis of diagnostic MRI (see *MRI in Clinical Medicine*). The poor contrast of this T_1 -weighted sequence for many pathologies was compensated for by the abundant use of MRI contrast agents (see *Contrast Agents in Magnetic Resonance: Operating Mechanisms*). With RARE, T_2 -weighted imaging, with its intrinsic high contrast for many pathological conditions, suddenly became routinely available due to the considerable time savings compared with conventional T_2 -weighted experiments afforded by the acquisition of several k -space lines per excitation. Currently, in most applications the experiment is performed in several excitation cycles with the acquisition of 3–48 differently phase-encoded echoes per excitation. Single shot implementations with echo times of 10–25 ms have led to new applications such as MR RARE myelography,³ urography,^{4,5} and cholangiography,⁶ the unique contrast behavior of which has opened up new avenues for clinical diagnosis using MRI.

With the current introduction of fast gradient systems into clinical MRI, single shot RARE applications with acquisition times below 1 s have become feasible. With the availability of fast gradient systems, the rf power deposition due to the rapid repetition of refocusing pulses has become the limiting factor for acquisition speed. An echo interval of around 3.5–5 ms appears to be minimal for routine clinical applications. Various developments based on fast gradient systems are discussed in Section 3.3.

2 METHODOLOGY

The Carr–Purcell–Meiboom–Gill sequence makes use of an excitation pulse followed by a sequence of equally spaced 180°

Figure 1 Scheme of the RARE imaging sequence. rf, rf pulses and signals; G_S , G_R and G_P , the slice selection, readout, and phase-encoding gradients, respectively

refocusing pulses.⁷ If the phase of the refocusing pulses is shifted by 90° with respect to the excitation pulse, and if the spacing between refocusing pulses is twice the time between the excitation pulse and the first refocusing pulse, this sequence is self-refocusing against effects from imperfect pulse flip angles, in the sense that the resulting errors do not accumulate over the length of the echo train, but rather average out to some steady state contribution. The problem in using this sequence as the basis of a MRI experiment lies in the difficulties in preserving the self-refocusing properties under the conditions of switched gradient fields. It has been demonstrated that this requires the use of gradients such that the spin dephasing caused by the phase-encoding gradient in each refocusing period is equal to twice the dephasing caused by the same gradient in the interval between the excitation pulse and the first refocusing pulse. The application of this principle has led to the introduction of the RARE sequence^{2,3} shown in Figure 1. The dephasing caused by the phase-encoding gradient between two successive rf pulses is brought to zero by means of a phase-encoding rewinding gradient after each echo and before the following rf pulse. The disastrous image artifacts that arose in previous attempts to perform multi echo acquisition are thus avoided.

It has also been demonstrated that flip angles of the refocusing pulses as low as 60° can be used, which significantly reduces the rf absorption problems mentioned above.⁸ A thorough description of the behavior of spin systems in multi-pulse sequences under the conditions of time-variable magnetic field gradients based on the papers of Hahn⁹ and Woessner¹⁰ is given by Ahn et al.¹¹ It should be noted that artifact-free images can only be generated if the total phase of the spin system under observation is brought to exactly the same state prior to each refocusing pulse. Temporal variations in the magnetic field caused by eddy currents arising from the

effect of the switched magnetic field gradients are disastrous for the stability of the sequence. This factor delayed the widespread clinical use of the sequence until the beginning of the 1990s.

The assessment of the contrast in RARE images is somewhat complicated by the fact that data are acquired at different echo times. This leads to an unequal T_2 -weighting of different k -space lines, which not only affects the final pixel intensities, but also the point spread function of different structures. Since most of the signal intensity in a typical clinical image is concentrated around the lower order phase-encoding steps, the overall image contrast is determined by the T_2 -weighting of the corresponding echoes.^{2,12,13} Narrow structures with a more even distribution of signal intensities over k -space are affected differently than broad structures with a corresponding narrow intensity distribution in k -space. In general, RARE sequences produce some edge enhancement, thus overemphasizing narrow structures and interfaces between tissues.

The distribution of k -space data over the various echoes occurring at different times is thus a very important factor influencing the image contrast. Figure 2 shows a series of images, all of which were acquired with identical parameters except for the distribution of phase-encoding steps. In all images, phase encoding was applied such that the distribution of T_2 -weighting of the data in k -space was as smooth as possible. The difference in contrast in the images shown arises from a shift of the phase-encoding zero point along the echo train. Phase encoding zero in late echoes leads to heavier T_2 -weighting. An interleaved consecutive phase-encoding scheme was proposed in the original RARE paper.² Later, a corresponding centric phase-encoding approach was demonstrated as an alternative.^{12,13} Both strategies allow a wide variation of the image contrast.

Figure 2 A series of sagittal RARE images acquired with identical timing parameters (echo interval 20 ms, 8 echoes per excitation, 2800 ms recovery time) but different phase-encoding schemes. The phase encoding zero point was placed at $TE = 140$ ms (a), 80 ms (b), 60 ms (c), and 40 ms (d). (e) The anatomical position of the images. (2 T, Bruker S 200 F, University Freiburg)

3 APPLICATIONS

3.1 Clinical Applications using Segmented Acquisition

Although the clinical usefulness of RARE images has been demonstrated since 1986,^{3,14} the widespread proliferation of RARE sequences into routine clinical practice began only in 1990, aided by the availability of actively shielded gradient systems (see *Gradient Coil Systems*)^{11–13,15–31} and originating in the work done by Jolesz, Mulkern and their

Figure 4 RARE (TSE) image of a patient with a chondrosarcoma. (a) Pelvic bones, (b) muscles, (c) subcutaneous fat, (d) tumor, (e) bowel. ($TR/TE=4650/16$, 25 echoes per excitation; 1 T, Siemens Magnetom, University Freiburg)

co-workers. With the echo times of 10–20 ms achievable at that time, it was clear that segmented acquisition was the best option for achieving a contrast relevant effective echo time of 60–100 ms. Between 3 and 8 echoes per excitation are commonly used in this acquisition mode, leading to a time saving of roughly the same factor. For multislice applications, where the recovery time between successive excitations of the same slice is filled with measurements in adjacent slices, the time saving may be less, since the repetition time might have to be increased in order to accommodate the longer acquisition time per slice resulting from the long echo train.

Clinically, the most relevant area of application for this experiment is the diagnosis of lesions in the central nervous system (see *Intracranial Infections; Head and Neck Investigations by MRI; Magnetic Resonance Imaging: A Historical Overview*). Most tumors and metastasis show up brightly in T_2 -weighted scans, as do demyelinating lesions, edema and various types of inflammatory lesions. An example is shown in Figure 3. For examinations of the abdomen, T_2 -weighted scans also deliver important diagnostic information, as shown in Figure 4. For imaging of the extremities, a stronger T_1 contrast is normally used (Figure 5). Acquisition times below 20 s, which allow the examination to take place within one breath-hold, are especially important for examinations of the upper abdomen. With state-of-the-art gradient systems, such applications have become feasible (Figure 6). High-resolution multislab three-dimensional examinations with a 512×512 matrix have also been demonstrated to be feasible with short

Figure 5 RARE (TSE) image of the knee showing a metastasis of a lymphoma (f) in the tibia. (a) Femur, (b) tibia, (c) patella, (d) muscles, (e) crucial ligament. ($TR/TE=600/15$, 3 echoes per excitation; 1 T, Siemens Magnetom, University Freiburg)

acquisition times.²⁴ In addition, dual-contrast sequences, which use groups of early echoes for the reconstruction of more spin density weighted images and groups of late echoes for T_2 -weighted imaging,¹⁵ have been used successfully.

Figure 6 RARE (FSE) image of the abdomen acquired within one breathhold, illustrating the lack of respiratory artifact. 3.2 RARE Myelography, Urography, and Cholangiography

Segmented RARE imaging delivers images with an information content which is (nearly) identical to that of a conventional T_2 -weighted image. The advantage of RARE lies in its considerable time saving. Applications of multi echo acquisition, for which no reasonable conventional technique appears to be feasible, are described in Section 3.3. In these experiments, multi echo acquisition is achieved by creating one long echo train after a single excitation of the spin system.^{2,3} By placing the zero phase-encoding step into an echo occurring at 500–1000 ms after excitation, all the signal from soft tissue is suppressed to well below 0.001% due to its typical relaxation time of 50–100 ms. Signals from body fluids, however, will appear bright because their T_2 is 1–3 s. The acquisition therefore selects fluid filled parts of the body. This allows acquisition without slice selection (Figure 7), which is of particular importance for structures of highly complicated geometric shape such as the cerebrospinal spaces^{3,30} (Figure 8), the urinary tract^{4,5} (Figure 9), and the hepatobiliary system⁶ (Figure 10), which are notoriously difficult to image using any slice selective technique.

The short acquisition times of 2–3 s per image allow the generation of views under different projection angles within very short total acquisition times, as well as studies of temporal changes over several seconds. The application of this experiment to three-dimensional acquisition has also been demonstrated.^{13,32}

3.3 Recent Developments

The faster gradients that are now becoming available allow a reduction of the echo time. The use of such fast gradients for the generation of a multislice dataset acquired within one breathhold has already been mentioned. For multislice applications it should be noted that it might not be the optimum solution to acquire images in consecutive single shots mode. An interleaved sequential acquisition using the same total acquisition time might be preferable in terms of image contrast and signal-to-noise ratio. An example of a volunteer image acquired with a single scan using an echo interval of 6 ms is shown in Figure 11.

Faster acquisition times are feasible if more than one signal is produced between successive refocusing pulses by gradient inversion.³³ The resulting GRASE sequence has been demonstrated to produce high-resolution images within very short acquisition times (Figure 12). The penalty for the decreased acquisition time is the sensitivity of GRASE images to T_2^* effects (see above), although to a lesser degree than that of pure echoplanar imaging. Clinical practice will show whether

applications can be found where the higher speed of GRASE outweighs the reliability and robustness of the RARE sequence.

Other recent developments in multi echo acquisition techniques use various schemes in order to introduce additional contrast mechanisms into the basic sequence. This includes pre-pulses for T_1 weighting by inversion-recovery^{34,35} for the suppression of signal from cerebrospinal fluid (brain water) for the better discrimination of lesions (Figure 13). A different approach called U-FLARE was pioneered by Norris³⁶ on an animal scanner. It uses various preparation sequences leading to magnetization transfer, motion, and diffusion weighting or additional spatial selection. The application of these experiments to whole body systems presents the very promising possibility of combining contrast manipulation with the inherently robust and self-refocusing properties of the RARE experiment. The resulting image contrast has been demonstrated to be highly relevant for applications such as early diagnosis of infarcts and asphyxia, and for novel applications such as functional imaging of brain activity (see *Brain*

Multiple Quantum Coherence Imaging

Timothy J. Norwood and Laurie D. Hall

Cambridge University, UK

1 INTRODUCTION

In both NMR spectroscopy and imaging, the precessing nuclear magnetization of the sample is detected. This magnetization corresponds to single quantum coherence, that is those coherences between pairs of states for which $\Delta M_T = \pm 1$, where ΔM is the overall change in magnetic quantum number between those two states. Multiple quantum coherences^{1,2} are all those coherences for which $\Delta M_T \neq \pm 1$, and which are consequently ‘spin forbidden’ and cannot be either excited or detected directly. For spin- $\frac{1}{2}$ nuclei, multiple quantum coherences can only be excited between a group of interacting spins (two for a zero or double quantum coherence, three for a triple quantum coherence), since for a single spin $\Delta m = \pm 1$.

A diagram of a system of two interacting spin- $\frac{1}{2}$ nuclei is given in Figure 1. In addition to the four allowed single quantum transitions (solid lines), this spin system contains a zero quantum transition, for which $\Delta M_T = 0$ (diagonal dashed line), and a double quantum transition (vertical dashed line), for which $\Delta M_T = \pm 2$. For nuclei with spins greater than $\frac{1}{2}$, some multiple quantum coherences can be excited from a single spin; for example, double as well as single quantum coherence can be excited from a spin-1 nucleus.

Interest in multiple quantum coherences arises from the fact that their properties are different from, yet complementary to, those of single quantum coherence.² In general, the precessional frequency of a coherence is given by:

$$\begin{aligned}\omega_{MQC} &= \sum_k \Delta m_k (1 - \sigma_k) \gamma_k B_0 \\ &= \sum_k \Delta m_k \omega_k\end{aligned}\quad (1)$$

Figure 1 Energy level diagram of an AX spin system. In addition to the four allowed single quantum transitions there are two forbidden transitions: a zero quantum transition (diagonal dashed line) and a double quantum transition (vertical dashed line)

where Δm_k is the change in magnetic quantum number of the spin k between the two states, and $\omega_k = (1 - \sigma_k) \gamma_k B_0$. Consequently, it can be seen that the precessional frequency of a multiple quantum coherence will be a linear combination of those of its active spins k . For example, a zero quantum coherence between spins l and m will precess at $(\omega_l - \omega_m)$.

If the effect of a spatially dependent variation in B_0 , $\Delta B(r)$, is included, equation (1) becomes:

$$\omega_{MQC} = \sum_k \Delta m_k [\omega_k + (1 - \sigma_k) \gamma_k \Delta B(r)] \quad (2)$$

Since $\sigma \ll 1$ and, usually, $\Delta B(r) \ll B_0$, equation (2) can be reduced to:

$$\omega_{MQC} = \sum_k \Delta m_k [\omega_k + \gamma_k \Delta B(r)] \quad (3)$$

It can be seen from equation (3) that the sensitivity of a homonuclear coherence to $\Delta B(r)$ will be directly proportional to its order. Thus, while a single quantum coherence will experience $\gamma \Delta B(r)$, a double quantum coherence will experience $2\gamma \Delta B(r)$, and a zero quantum coherence is completely unaffected. $\Delta B(r)$ may equally well be due to variations in the static magnetic field B_0 , or an applied magnetic field gradient. While a magnetic field gradient may be useful for encoding spatial information in an image, in a spectrum it is a nuisance, causing lines to broaden and thus decreasing resolution. While variations in the magnetic field will broaden double quantum lines twice as much as those of single quantum coherences, the zero quantum spectrum will be completely unaffected, and will consequently remain at high resolution.

The scalar couplings of multiple quantum coherences are also linear combinations of those of their active spins:

$$J_{MQC} = \sum_k \Delta m_k J_{kl} \quad (4)$$

where l is a passive spin. Multiple quantum coherences do not exhibit scalar couplings between their active spins.

2 MULTIPLE QUANTUM EXPERIMENTS

As noted above, multiple quantum coherences are ‘spin forbidden’ and consequently cannot be excited directly by the application of a single nonselective rf pulse to the equilibrium magnetization of a spin system, nor can they be detected directly since they have no net magnetization associated with them. Consequently, both these processes are usually achieved indirectly using a sequence of pulses. A multiple quantum pulse sequence can be regarded as consisting of four modules: an excitation module, an evolution module, a mixing module, and a detection module. During the excitation module, multiple quantum coherence is created from the equilibrium magnetization of the spin system, while during the evolution module it is allowed to evolve, sampling its environment. During the mixing module, the multiple quantum coherence is reconverted into an observable single quantum coherence which is subsequently detected. To obtain a multiple quantum spectrum it is necessary to repeat the experiment a number of times, systematically incrementing the length of the evolution module t_1 .

This introduces a modulation into the observed signal as a function of t_1 and the multiple quantum frequency, and consequently Fourier transformation with respect to t_1 will yield the multiple quantum spectrum.

The excitation module typically consists of the pulse sequence:

$$90_x^\circ(\tau/2)180_y^\circ(\tau/2)90_\theta^\circ$$

where $\theta = x$ if even orders of coherence are to be excited, and $\theta = y$ when odd orders are required. Typically, $\tau = (\frac{1}{4}J)$. The effect of this pulse sequence, when $\theta = x$, on the magnetization of a spin k coupled to a spin l is, in the product operator formalism:³

$$I_{kz} \xrightarrow{90_x^\circ} -I_{ky} \xrightarrow{\tau} 2I_{kx}I_{lz} \xrightarrow{90_x^\circ} -2I_{kx}I_{ly}$$

where I_{ky} corresponds to in-phase y magnetization of spin k , $2I_{kx}I_{lz}$ corresponds to x magnetization of spin k antiphase due to its scalar coupling to spin l , and $2I_{kx}I_{ly}$ describes a linear combination of zero quantum and double quantum coherence with active spins k and l . The first 90° pulse excites in-phase magnetization which subsequently becomes antiphase during τ due to any scalar couplings present. This antiphase single quantum coherence is converted into multiple quantum coherence by the second 90° pulse. The 180° pulse refocuses chemical shift evolution and any dephasing due to magnetic field inhomogeneity during τ . For spin- $\frac{1}{2}$ nuclei in the slow tumbling regime, relaxation may take the place of scalar coupling evolution during τ in converting in-phase into antiphase magnetization.

The evolution module typically consists of a single delay t_1 which may be incremented in consecutive experiments when multiple quantum spectra are to be acquired (see above) or set to zero when the sequence is being used solely to achieve multiple quantum filtration (see below). The mixing module is essentially the reverse of the excitation period, except that it converts the multiple quantum coherence back into transverse instead of longitudinal magnetization. The FID is observed during the detection module.

Usually, a single order of coherence is selected during the evolution module. This is achieved by using either phase cycling or magnetic field gradient pulses. The latter has the advantage that only a single experiment is required to achieve selection, which is often much cleaner than the corresponding phase cycled experiment, although up to half of the signal may be lost.

3 PRACTICAL CONSIDERATIONS

The nature of multiple quantum coherences dictates the structure of pulse sequences suitable for multiple quantum NMR. This structure, and in particular the necessity of using multiple pulse excitation and mixing sequences, has important consequences for the practicality of multiple quantum techniques in the context of NMR imaging and in vivo spectroscopy.

The efficiency of the excitation sequence in particular is parameter dependent. As noted in the previous section, the length of the excitation sequence is usually set to $\frac{1}{4}J$ since,

although this does not produce the maximum intensity of any particular coherence, it does, in principle, produce a relatively uniform distribution of coherence intensities. However, in practice, the size of scalar couplings may vary considerably and as a consequence so will coherence intensities. Furthermore, transverse relaxation times in vivo are frequently short, resulting in an additional loss of signal intensity during the excitation and mixing sequences. These two factors—the limited efficiency of multiple quantum excitation (and to a more limited degree reconversion of multiple quantum into single quantum coherence during the mixing module) and transverse relaxation—combine to limit the usefulness of multiple quantum techniques in many applications. Imaging magnets are usually of relatively low magnetic field strengths (typically no more than 2 T). Consequently, sensitivity is at a premium, and additional losses, such as those arising during multiple quantum experiments, can ill be afforded.

4 APPLICATIONS

4.1 Zero Quantum Coherence Chemical Shift Imaging

The samples studied by NMR imaging are often both large and heterogeneous compared to their high resolution counterparts. As a consequence, variations in the static magnetic field B_0 and internal magnetic field gradients arising from susceptibility variations across the sample may both cause a broadening of the transitions in the conventional single quantum spectrum. As a result of this, peaks in the single quantum spectrum may overlap, making it impossible to obtain separate chemical shift resolved images of different chemical species.

Homonuclear zero quantum coherence offers a solution to this problem, since it is intrinsically independent of magnetic field inhomogeneity. By replacing the encoding of single quantum with zero quantum chemical shift it is possible in a chemical shift resolved imaging experiment to produce resolved images of different chemical species, independent of any variations in the magnetic field.^{4,5} The pulse sequence for a zero quantum coherence chemical shift resolved imaging experiment is shown in Figure 2. As with most subsequent multiple quantum imaging experiments, spatial encoding takes place in the mixing and detection periods. The slice selection gradient is pulsed during the evolution period to dephase the nonzero quantum coherences. An example of the application of this experiment using a phantom is given in Figure 3. While a three-dimensional data set correlating two spatial dimensions against zero quantum chemical shift can be obtained by incrementing the zero quantum evolution period t_1 independently of the phase-encoding gradient, in this example the two have been incremented simultaneously to produce a series of images displaced by the relevant zero quantum frequency in the F_1 dimension. A disadvantage of this technique, common to all zero quantum experiments, is the presence of an intense peak at $F_1 = 0$ arising, not from zero quantum coherence, but from magnetization that is longitudinal during the evolution period; the two cannot be separated by using either phase cycling or magnetic field gradient pulses, since they have identical phase properties.

Figure 2 Pulse sequence for zero quantum coherence chemical shift resolved imaging. $t = (\frac{1}{4}J) - (\frac{1}{2}J)$ coherence transfer pathway selection is achieved using the magnetic field gradients

4.2 Double Quantum Coherence Phase Encoding

The sensitivity of multiple quantum coherences to magnetic field gradients is put to further use in an experiment which uses double quantum coherence for phase encoding⁶ (Figure 4). Unlike the experiment described above where zero quantum coherence may be used because of its insensitivity to magnetic field gradients, here double quantum coherence is used because of its increased sensitivity with respect to single quantum coherence. Since double quantum coherence is twice as sensitive to magnetic field gradients as is single quantum coherence, a phase-encoding gradient applied to it need only be half the amplitude or half as long as one applied to the latter to achieve the same effect. However, any advantage gained through this procedure would seem to be lost in the increased length of the experiment resulting from multiple quantum excitation, unless a particularly long delay is required for T_2 -weighting or if double quantum T_2 -weighting is required.

In the pulse sequence shown in Figure 4 a magnetic field gradient rather than phase cycling was used to select the desired coherence transfer pathway. The double quantum coherence is dephased by pulsing the frequency-encoding gradient. After reconversion into single quantum coherence, a coherence transfer echo is formed in the presence of the final frequency-encoding gradient, which is observed. Magnetization that followed other pathways will form echoes at different times, and consequently coherence transfer pathway selection can be achieved in a single scan. It should be noted that the signal intensity will only be half of that obtained using phase cycling.

4.3 Multiple Quantum Filtration

Multiple quantum filtration provides a quick and easy to implement method of separating out the magnetization of nuclei according to the number of scalar coupling partners that they have. Unlike most other techniques used for in vivo spectroscopy and imaging, no prior knowledge of the frequencies of individual resonances and no soft pulses (except for spatial localization, where applicable) are required. Three types of multiple quantum filtration experiment have been demonstrated: double quantum filtration of spin- $\frac{1}{2}$ nuclei, double quantum and triple quantum filtration of spin- $\frac{3}{2}$ nuclei, and heteronuclear zero quantum and double quantum filtration of ^1H magnetization coupled to ^{13}C .

Double quantum filtration of spin- $\frac{1}{2}$ nuclei has been used for both ^1H spectroscopy and imaging.^{7,8} While both phase cycling and magnetic field gradient pulses can be used to select the relevant coherence transfer pathways, the latter are often preferred because, although their use results in an additional reduction in signal intensity, they are quicker since no signal averaging is required, and they are less sensitive to motion artifacts. The main rationale for the use of double quantum filtration is as a form of water suppression. It has the advantage over most other types of water elimination procedure in that the lines in the spectrum do not have to be resolved from each other and no selective pulses are required in the procedure. Furthermore, unlike most other techniques, any signal from coupled nuclei underneath the water signal is not suppressed. A typical double quantum filtered imaging sequence is shown in Figure 5. Spatial encoding is accomplished in the period following

Figure 3 ^1H zero quantum image of a phantom consisting of vials of 2-propanol, propionic acid, and water obtained using the pulse sequence given in Figure 2. The zero quantum evolution period t_1 and the phase-encoding gradient were incremented simultaneously to produce images of each chemical species centered on its zero quantum chemical shift

reconversion of double quantum into single quantum coherence. The gradient pulses during the preparation period serve to dephase magnetization not following the desired coherence transfer pathway. The 180° pulse during the multiple quantum evolution period reverses chemical shift evolution and dephasing due to magnetic field inhomogeneities. An example of data acquired with this pulse sequence is given in Figure 6. A two-step phase cycle is used; adding data from the two steps produces a single-quantum image, while subtraction produces a multiple-filtered image.

Double quantum and triple quantum filtration has been used to separate the signals from intracellular and extracellular sodium.^{9–11} The nature of the intracellular milieu tends to give rise to long correlation times, which in the case of spin- $\frac{3}{2}$ nuclei results in biexponential relaxation. Multiexponential relaxation in spin- $\frac{3}{2}$ nuclei such as ^{23}Na has a similar effect to scalar couplings in spin- $\frac{1}{2}$ nuclei—it causes evolution between in-phase and antiphase magnetization. Antiphase magnetization, whatever its origin, can be converted into multiple quantum coherence. Consequently, intracellular ^{23}Na will be passed by double quantum and triple quantum filtration, while extracellu-

lar sodium, which relaxes monoexponentially, will not. These effects have been used to produce both edited spectra and images of intracellular sodium.

Heteronuclear multiple quantum filtration has been used to produce spectra and images of ^1H magnetization coupled to ^1X ; ^1H magnetization that does not meet this criterion is removed.^{12,13} Editing is achieved with a one-dimensional version of the heteronuclear multiple quantum coherence (HMQC) experiment in which heteronuclear zero quantum and double quantum coherence is excited. While, for reasons of sensitivity due to the low natural abundance of ^{13}C this has not yet been used in vivo, it is likely to be a useful tool when used in conjunction with ^{13}C labeling.

Partial Fourier Acquisition in MRI

Paul M. Margosian, Gordon DeMeester, and Haiying Liu

Picker International, Highland Heights, OH, USA

1 INTRODUCTION

The original motivation for exploring partial Fourier image reconstruction methods for MRI was the possibility of completing an acquisition in roughly half the normal time. For standard multislice spin echo methods, this means that a typical acquisition might be reduced from 10 to 5 min. Such possibilities offer the potential of increasing the efficiency, both clinical and economic, of a commercial magnetic resonance (MR) imager.

The most basic partial Fourier acquisition is to acquire the central 128 lines of the raw data space, zero fill the outer lines [Figure 1(a)], and take the amplitude of the Fourier transform (FT) to make a 256×256 image which has sacrificed spatial resolution in the phase-encode direction. This is a basic property of FTs,¹ and is equivalent to making a sinc interpolation of a 128×256 image up to full size.²

Another basic manipulation is to acquire only every second phase-encode line (Figure 1(b)) of a normal set of 256, and

Figure 1 (a) Center 128 data lines; (b) all other data lines

Figure 2 $N/2 + L$ data lines in (a) the phase-encode direction and (b) the read direction

seek various interpolation methods to approximate the missing data lines in an attempt to maintain full spatial resolution. Such an attempt is doomed to failure by the sampling theorem;¹ the result of such an experiment is invariably an image with accompanying ghost images that may overlap the main image, the relative amplitude of which reflects the importance of the spatial frequencies that could not be faithfully reproduced. Only iterative methods which insert additional constraints and a priori information are suitable to make such a strategy work.

The most widely used partial Fourier methods take advantage of the fundamental redundancy of complex samples of the signals acquired to provide a full resolution reconstruction from half the raw data, using all the samples on one side of the echo (in either the phase-encode direction [Figure 2(a)] or the readout direction [Figure 2(b)]). Of the most commonly used 'single-pass' methods, one is based on an approximate deconvolution of the data 'blanking' function which represents missing data,^{3,4} while the other is based on explicit calculation of missing raw data by assuming that the full data set (of which only half has been acquired) is Hermitian⁵ and therefore that the image is strictly real. These methods achieve full spatial resolution at the cost of a loss of approximately a factor of $\sqrt{2}$ in the signal-to-noise ratio. They require acquisition of a few more than half the normal number of data lines in order to allow generation of a low-frequency phase correction which is

needed in order to remove the effects of practical instrument imperfections from the raw data. More elaborate iterative methods have been reported⁶⁻⁹ which seek to overcome more complicated errors at the cost of much increased computation time; an exposition of such algorithms in the more general context of constrained reconstruction methods is given by Liang et al.¹⁰

This article describes the two most commonly used ‘single pass’ half Fourier methods and provides an example of one type of iterative method. These methods are sometimes referred to as ‘phase constrained’ reconstructions.

2 MATHEMATICAL BACKGROUND

2.1 General Considerations

For the ideal MRI application, the spin system of the imaged object (the patient) is a real function. First-order gradients of a z directed magnetic field phase-encode the data as the FT of the excited spin system. Such measurements form a two- or three-dimensional k -space, or spatial frequency space, representation of the object.

In practice, the phase-encoding process, and consequently the k -space data, are not ideal. Possible errors include uncorrected time dependence of the gradient field as with eddy currents. Furthermore, signal from the spin system is likely to decay with time constants such as T_2 and T_2^* in the read direction. Even rf imperfections can disturb the phase. Such errors cause uncontrolled phase variations across the k -space, but preserve the amplitude. This means that the phase of a complex MR image is not really zero and that partial Fourier reconstruction algorithms which appeal to the special kind of symmetry of ideal data will be distorted unless an appropriate phase correction is devised.

2.2 Notation

The partial Fourier methods discussed all seek to recover an image from slightly more than half of k -space (Fourier encoded raw data in Cartesian coordinates). In principle, it does not matter if the data set is one-, two-, or three-dimensional, as long as it is incomplete in only one spatial frequency coordinate, and it is equivalent for the data to be incomplete in either a phase-encode direction or a read direction. In practice, however, data variations in the phase direction are more nearly ideal than in the read direction. The acquired data are represented by $D(k_1, k_2, k_3)$, where the data are assumed to be complete in the k_1 and k_2 spatial frequency dimensions, and incomplete in the k_3 direction. When discussing Fourier reconstruction, the corresponding spatial variables are x_1, x_2 , and x_3 , respectively; the transforms are done sequentially for the axes having complete data (k_1 and k_2), and the partial Fourier algorithms are applied only to the incomplete (k_3) axis. The notation used to denote the partially transformed data is $D(x_1, x_2, k_3)$, where

$$D(x_1, x_2, k_3) = \text{IFT}_{(k_1, k_2)}[D(k_1, k_2, k_3)] \quad (1)$$

and IFT is the inverse Fourier transformation. Reduction to two dimensions is straightforward.

In all the algorithms described for completing the transformation in the k_3 direction, the number of data lines acquired is described as $N/2 + L$, where N is the (full) image matrix size, and L is the number of extra lines which has been taken past the center of k -space. The central $2L$ data lines are used to generate a low-frequency phase estimate of the completed complex image.

2.3 Minimizing Ringing Artifacts

Truncation of k -space is always a problem with digital data acquisition because of the limited extent of the sampling; the presence of significant object information beyond the end of k -space sampling will cause Gibbs ringing.² This kind of artifact is best controlled by sampling far enough in k -space to satisfy the sampling theorem for the data present. In the cases discussed here, there are always too few samples in one dimension and, therefore, truncation artifacts are minimized by using the Hanning filter $H(k_3)$ which varies smoothly from one to zero over $L + 1$ points.² Exact details of the application of this filter are given with each partial Fourier algorithm.

2.4 Phase Correction Method

All partial Fourier methods to be discussed require at least a low-frequency phase correction to the MRI data for proper functioning. Typical phase errors consist of an arbitrary overall phase constant plus a limited excursion of a few π across a complex image. Thus it is reasonable to estimate phase variations by a phase map generated from the central 8–15% of the data lines of k -space; the exact number of lines is an adjustable parameter. A low-resolution phase correction is generated as described below.

The phase map estimate $\phi_L(x_1, x_2, x_3)$ is determined from the central $2L$ lines of k -space with zero padding. A Hanning weighting $H(k_3)$ is applied to these central data in order to minimize the potential for ringing artifacts. The raw data P are used for the phase correction:

$$P(x_1, x_2, k_3) = D(x_1, x_2, k_3) * H(k_3) \quad -L \leq k_3 \leq +L \quad (2a)$$

$$P(x_1, x_2, k_3) = 0.0 \quad \text{Elsewhere} \quad (2b)$$

where we have followed the notation established in Section 2.2. The inverse FT in the k_3 variable is then calculated:

$$p(x_1, x_2, x_3) = \text{IFT}_{k_3}[P(x_1, x_2, k_3)] \quad (2c)$$

A low-frequency phase map can be formed from p :

$$\phi_L(x_1, x_2, x_3) = \arctan \left[\frac{\text{Im}[p(x_1, x_2, x_3)]}{\text{Re}[p(x_1, x_2, x_3)]} \right] \quad (3)$$

Note that this phase map exists in the complex image domain (i.e. the independent variables are spatial coordinates, not spatial frequencies). An alternative way to accomplish the desired phase correction is to compute a normalized version u of the (blurry) complex image $p(x_1, x_2, x_3)$:

$$u(x_1, x_2, x_3) = p(x_1, x_2, x_3) / |p(x_1, x_2, x_3)| \quad (4)$$

The complex conjugate of u , u^* , can be used to make an approximate phase correction to complex images made from the

acquired data. The function u itself is used to correct phases of data sets synthesized by Hermitian conjugation. The effect of such a correction is to make the complex image more nearly real.

3 HALF FOURIER, DECONVOLUTION APPROACH

3.1 Theory for the Ideal Case

The half Fourier method is a technique for recovering an image from slightly more than half of k -space data coverage, in which one treats the problem of recovering the full image as equivalent to deconvolving the effects of the data truncation from the complex image domain.

Assume that exactly half of a three-dimensional data set exists. Then each of the (partially transformed) data lines $D(x_1, x_2, k_3)$ can be thought of as the product of the object data $O(x_1, x_2, k_3)$ and a unit step function $S(k_3)$:

$$D(x_1, x_2, k_3) = O(x_1, x_2, k_3) * S(k_3) \quad (5)$$

The image recovery process includes the FT of the data:

$$d(x_1, x_2, x_3) = \text{IFT}_{k_3}[D(x_1, x_2, k_3)] \quad (6)$$

Using the convolution theorem with equations (5) and (6) gives the result

$$d(x_1, x_2, x_3) = O(x_1, x_2, x_3) \otimes s(x_3) \quad (7)$$

where $o(x_1, x_2, x_3)$ is the desired object information and the FT of the step function is

$$s(x_3) = \frac{1}{2}[\delta(x_3) + i/\pi x_3] \quad (8)$$

and δ is the Dirac delta function. Now assume that we can find a phase map $\phi(x_1, x_2, x_3)$ for the object $o(x_1, x_2, x_3)$ that reduces this complex image to a real image $r(x_1, x_2, x_3)$:

$$r(x_1, x_2, x_3) = o(x_1, x_2, x_3) * \exp[-i\phi(x_1, x_2, x_3)] \quad (9)$$

This phase map (Section 2.4) is that which would be generated from the data of the object $O(x_1, x_2, x_3)$ if it existed. Finally,

$$\begin{aligned} d(x_1, x_2, x_3) * \exp[-i\phi(x_1, x_2, x_3)] \\ = r(x_1, x_2, x_3) \otimes s(x_3) \\ = r(x_1, x_2, x_3)/2 - i\{r(x_1, x_2, x_3) \otimes 1/2\pi x_3\} \end{aligned} \quad (10)$$

The image that we wish to recover is $r(x_1, x_2, x_3)$. It can be determined from

$$r(x_1, x_2, x_3) = \text{Re}[d(x_1, x_2, x_3) * \exp[-i\phi(x_1, x_2, x_3)]] \quad (11)$$

3.2 Practical Implementation

The half Fourier method follows the ideal theory except in the details of the Hanning filtering of the central lines in order to avoid truncation effects.

1. Acquire the data set, inverse FT in the complete data directions.
2. Find the phase map ϕ , or normalized correction function u , as in Section 2.4.

3. Recover the image. This requires both the phase estimate and a Hanning roll-off filter. The filtered data, D_f are formed by using weight factors that range from one for the element $-L$ down to zero for the element $+L$:

$$D_f(x_1, x_2, k_3) = D(x_1, x_2, k_3) \quad -N/2 \leq k_3 < -L \quad (12a)$$

$$D_f(x_1, x_2, k_3) = D(x_1, x_2, k_3) * H(k_3) \quad -L \leq k_3 < +L \quad (12b)$$

$$D_f(x_1, x_2, k_3) = 0.0 \quad \text{Elsewhere} \quad (12c)$$

Now inverse FT the filtered data:

$$d(x_1, x_2, x_3) = \text{IFT}_{k_3}[D_f(x_1, x_2, k_3)] \quad (13)$$

Finally, recover the desired image by applying equation (11):

$$\begin{aligned} r(x_1, x_2, x_3) &= \text{Re}[d(x_1, x_2, x_3) * u^*(x_1, x_2, x_3)] \\ &= \text{Re}[d(x_1, x_2, x_3) * \exp[-i\phi_L(x_1, x_2, x_3)]] \end{aligned} \quad (14)$$

The result is a simple and fast method of making images from slightly more than half the data. The signal-to-noise ratio is proportional to the number of phase-encode lines acquired; therefore, with half Fourier imaging we expect the signal-to-noise in the image to be reduced by $1/\sqrt{2}$ compared with a conventional complete data set.

4 CONJUGATE SYMMETRY APPROACH

4.1 Theory for the Ideal Case

Ideally, the spin system of the imaged object or patient is real, and therefore its FT is conjugate symmetric (Hermitian). The conjugate symmetry relation for an ideal three-dimensional data set $D(k_x, k_y, k_z)$ can be written as

$$D(k_x, k_y, k_z) = D^*(-k_x, -k_y, -k_z) \quad (15)$$

It is clear from equation (15) that half the ideal k -space data are redundant. A statement of conjugate symmetry at an intermediate step of processing is

$$I(x_1, x_2, k_3) = I^*(x_1, x_2, -k_3) \quad (16)$$

4.2 Practical Implementation

The conjugate symmetry algorithm uses the conjugate symmetry relation in one dimension, a Hanning filter, and the phase estimate. The Hanning filter, whose weights vary from one to zero over $L + 1$ data lines, is used when synthesizing a complete data line. The method of combining these elements to generate the desired image $c(x_1, x_2, x_3)$ is described below.

1. Calculate the intermediate image $I(x_1, x_2, k_3)$ as in equation (16). This image spans the range of the variables x_1 and x_2 as well as variable k_3 .
2. Produce the phase estimate function u , as in Section 2.4.
3. Produce a partial image $a(x_1, x_2, x_3)$ from the acquired data:

$$A(x_1, x_2, k_3) = I(x_1, x_2, k_3) \quad -N/2 \leq k_3 < 0 \quad (17a)$$

$$A(x_1, x_2, k_3) = H(k_3) * I(x_1, x_2, k_3) \quad 0 \leq k_3 \leq L \quad (17b)$$

$$A(x_1, x_2, k_3) = 0.0 \quad k_3 > L \quad (17c)$$

Now inverse FT on the k_3 variable:

$$a(x_1, x_2, x_3) = \text{IFT}_{k_3}[A(x_1, x_2, k_3)] \quad (18)$$

The complex image $a(x_1, x_2, x_3)$ is then multiplied point by point by the complex conjugate of the phase image $u(x_1, x_2, x_3)$:

$$au(x_1, x_2, x_3) = a(x_1, x_2, x_3) * u^*(x_1, x_2, x_3) \quad (19)$$

4. Now use the conjugate symmetry relation to generate a partial image from the data that were not acquired,

$$B(x_1, x_2, k_3) = 0.0 \quad -N/2 \leq k_3 < 0 \quad (20a)$$

$$B(x_1, x_2, k_3) = \{1.0 - H(k_3)\} * I^*(x_1, x_2, -k_3) \quad 0 \leq k_3 \leq L \quad (20b)$$

$$B(x_1, x_2, k_3) = I^*(x_1, x_2, -k_3) \quad k_3 > L \quad (20c)$$

and then FT in k_3 to make a partial image from the missing data,

$$b(x_1, x_2, x_3) = \text{IFT}_{k_3}[B(x_1, x_2, k_3)] \quad (21)$$

This intermediate image also needs to be multiplied by the phase map; use the unit phase map and not its complex conjugate for the point-by-point product:

$$bu(x_1, x_2, x_3) = b(x_1, x_2, x_3)u(x_1, x_2, x_3) \quad (22)$$

5. Compute the final image from the complex sum of the two intermediate images formed in steps 3 and 4 above:

$$c(x_1, x_2, x_3) = |au(x_1, x_2, x_3) + bu(x_1, x_2, x_3)| \quad (23)$$

Because of the use of the complex phase map the final image $c(x_1, x_2, x_3)$ is nearly real, therefore one may choose this presentation as an alternative to a standard magnitude image. The noise in a real image is not required to be positive, as with a magnitude image, so it maintains a zero mean Gaussian behavior near zero. The effectiveness of the phase map corrections may be estimated by looking at the residual imaginary image.

The signal-to-noise ratio in a full data set varies as $\sqrt{N}$. For the partial data set, the noise is averaged down inversely as the number of lines acquired. Since the region between $N/2 + 1$ and $N/2 + 1 + L$ is only weighted on average by $\frac{1}{2}$, the predicted signal-to-noise ratio (S/N) will scale as:

$$S/N \propto (N/2 + L/2 + 1)^{1/2} \quad (24)$$

5 ITERATIVE RECONSTRUCTION

When half or more of the data are acquired in any direction, iterative techniques can be devised to substitute, sequentially, synthesized data subjected to constraints for the missing data. One such method is referred to as the ‘Cuppen-POCS iterative method’.⁶

The theoretical development is similar to that used in the half Fourier or deconvolution method. However, the physical object is no longer represented by a real function but by the magnitude of a complex function. This would not be correct for the noise surrounding the object or for inversion–recovery imaging, but otherwise it is a reasonable constraint. The steps in the projection onto convex sets (POCS) method are as follows.

1. Acquire the partial Fourier data set $D(k_1, k_2, k_3)$ which is truncated in the k_3 direction.
2. Develop a phase map from the data lines $-L$ to $+L$, as in Section 2.4.
3. For the first iteration $m = 1$, replace the missing data with zero. For all subsequent iterations $m > 1$, replace the missing data with synthesized data $R(x_1, x_2, k_3)$ from the last iteration:

$$D_m(x_1, x_2, k_3) = D(x_1, x_2, k_3) \quad -N/2 \leq k_3 \leq +L \quad (25)$$

Then, for the first iteration

$$D_1(x_1, x_2, k_3) = 0.0 \quad +L < k_3 \leq N/2 \quad (26)$$

and for subsequent iterations

$$D_m(x_1, x_2, k_3) = R_{m-1}(x_1, x_2, k_3) \quad +L < k_3 \leq N/2 \quad (27)$$

4. Now take the inverse FT of the completed data set and apply the phase map $\phi_L(x_1, x_2, x_3)$ determined in step 2 above:

$$d_m(x_1, x_2, x_3) = \text{IFT}_{k_3}[D_m(x_1, x_2, k_3)] \quad (28)$$

$$r_m(x_1, x_2, x_3) = |d_m(x_1, x_2, x_3)| * \exp[-\{i\phi_L(x_1, x_2, x_3)\}] \quad (29)$$

5. The data to replace the original missing data from $+L$ to $N/2$ are determined from the FT of $r_m(x_1, x_2, x_3)$:

$$R_m(x_1, x_2, k_3) = \text{FT}_{x_3}[r_m(x_1, x_2, x_3)] \quad (30)$$

For the data replacement in step 3, only the values of k between L and $N/2$ will be used. For the last iteration a linear weighting scheme is used to ‘feather’, or merge, the replacement data with the original data in step 3. In this case a number of points before the boundary are used for the merge.

6. The desired image is $r(x_1, x_2, x_3)$, the output of step 4 after the desired number of iterations (typically three or four) is completed.

This sort of process has proven superior to both half Fourier and conjugate symmetry methods for partial Fourier reconstruction of gradient echo acquisitions where phase errors are severe. In this framework, it is also easier to incorporate more phase constraints into the image reconstruction. This procedure is somewhat more computationally intensive than are the one-pass methods.

6 CONCLUDING REMARKS

All three partial Fourier methods impose a phase correction determined from data near the center of k -space. Differences between the low-frequency phase map and the phase map

determined from a full (ideal) data set limit the accuracy of the techniques.

Both the half Fourier method and the conjugate symmetry methods assume a real object and use the same phase map, but are quite different operationally. Both methods use a Hanning filter, but in different ways: the half Fourier method applies this weight such that the center of k -space has a weight of 0.5, thus exacting a slight signal-to-noise penalty; the conjugate symmetry method applies the Hanning filter to weight the data from the center of k -space out to L . The conjugate symmetry method requires two inverse FTs, whilst the half Fourier method needs only one.

The three methods use assumptions about a real object differently. The half Fourier method requires that the imaginary part of the final image be discarded. The conjugate symmetry method generates a complex image with a small imaginary part, so a magnitude operation is performed. This imaginary part arises because the phase of the acquired data does not exactly match the low-frequency phase map. The iterative method also generates a complex image because the phase constraint is applied to the magnitude of the image. None of these methods properly reconstructs nonreal object features (in the Fourier representation) such as motion or susceptibility.

Projection–Reconstruction in MRI

Gary H. Glover and John M. Pauly

Stanford University, Stanford, CA, USA

1 INTRODUCTION

Projection–reconstruction (PR) refers to a family of magnetic resonance (MR) imaging techniques that scan through acquisition data space (k -space) along radial trajectories, rather than along the rectangular Cartesian trajectories of Fourier transform (FT) methods. The first MR images were made using 2D projection–reconstruction (2D PR).¹ PR methods remained dominant in MR imaging research until the advent of FT methods,² and in particular spin warp.³ The FT methods have significant advantages in off-resonance response, tolerance for nonideal gradient response, and ease of reconstruction. PR has more exacting hardware requirements, has difficulties with off-resonance spins, and is less efficient in its use of scan time. Recently, imaging hardware and reconstruction methods have improved to the point that PR methods are once again the subject of active research. PR methods have some unique capabilities that outweigh their disadvantages for particular applications. Some of these advantages are short echo times for imaging short T_2 species, and reduced flow and motion artifacts.

There are several different versions of PR imaging, each with different areas of application. All PR methods collect data along radial lines in k -space. One major distinction is whether the whole volume or a slice is imaged. In the latter case, some form of slice selection must be incorporated, which has implications for minimum echo time. The other distinction is whether a full diameter is collected, or only a radius. Collecting full diameters is more efficient in scan time, while collecting radii allows much shorter echo times.

One of the applications for PR methods is in imaging with very short echo times. In 3D PR a single hard pulse excitation is followed immediately with the PR acquisition gradients. There are no phase-encoding gradients to delay acquisition, as in FT methods. These very short echo times are essential for imaging intracellular ^{23}Na ⁴ and ^{11}B ,⁵ which have very short T_2 values. The low sensitivity and short T_1 values of these nuclei make 3D imaging the natural choice. For ^1H the case is slightly different owing to the high sensitivity and desired resolution of proton images. Three-dimensional PR ^1H imaging would require prohibitively long scan times and result in very large data sets. In this case slice selection is desirable. This can be accomplished without increasing the echo delay using interleaved half pulses.⁶ Applications include imaging lung parenchyma, which has short T_2^* due to susceptibility dephasing and short T_2 due to diffusion.⁷ (See *Lung and Mediastinum: A Discussion of the Relevant NMR Physics* and *Sodium-23 Magnetic Resonance of Human Subjects*.)

The other area where PR methods excel is in the nature of the artifacts produced by motion. With FT methods, respiratory, cardiac, or other forms of physiological motion cause ghost artifacts. These artifacts spread in the phase-encoding direction and result from either phase or amplitude inconsistencies from one acquisition (view) to the next.⁸ The artifacts are well focused into discrete ghosts when the motion is highly periodic, but can smear uniformly when the motion is random. Projection–reconstruction methods have been found to be more robust with respect to motion, often providing superior performance when imaging moving structures.⁹ This is true whether full diameters or radii are collected. Flow artifacts are also reduced with PR, because short echo times eliminate most spin dephasing. FT methods exhibit a displacement artifact when imaging oblique vessels due to the different times that the x and y positions are encoded, while simultaneous encoding in PR eliminates such artifacts.¹⁰ (See *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control*; *Whole Body Magnetic Resonance Artifacts*.)

Thus, PR methods find applications either when imaging species with short transverse magnetization decay times or when motion artifacts are an issue.

2 THEORY OF PROJECTION–RECONSTRUCTION

2.1 Central Slice Theorem

Consider an object with a (possibly complex) distribution $m(x, y)$ as shown in Figure 1(a). In addition to the spin density, $m(x, y)$ includes relaxation weighting and phase factors which result from off-resonance excitation. Projections of the object are obtained at many angles θ in the frame (r, l) , where the projection is defined as the line integral

$$P_\theta(r) = \int_C m(x, y) dl \quad (1)$$

in which C is the path described by

$$x \sin \theta - y \cos \theta = r \quad (2)$$

and the integration extends along C through the object. Taking the Fourier transform of P in equation (1) yields

$$\begin{aligned} \hat{M}_\theta(k) &\equiv \mathcal{F}(P_\theta(r)) = \int P_\theta(r) e^{ikr} dr \\ &= \int e^{ikr} dr \int_C m(x, y) dl \end{aligned} \quad (3)$$

Since the transformation between the (x, y) and (r, l) frames has unity Jacobian, equation (3) becomes

$$\hat{M}(k_x, k_y) = \int e^{i(k_x x + k_y y)} m(x, y) dx dy \quad (4)$$

where equation (2) has been substituted for r , and

$$\begin{cases} k_x \equiv k \cos \theta \\ k_y \equiv k \sin \theta \end{cases} \quad (5)$$

Figure 1 Projection–reconstruction geometry. (a) Projection $P_\theta(r)$ of an object with a distribution $m(x, y)$ consists of line integrals along parallel rays C at angle θ . (b) Corresponding k -space representation of projection data, collected either as a diameter or radius

Equation (4) will be recognized as the two-dimensional Fourier transform of m evaluated at (k_x, k_y) in k -space. Note that points along (k_x, k_y) are diameters in k -space, as shown in Figure 1(b). Therefore, each projection (or view) contributes data along a diameter in k -space at the angle θ . This is a conclusion of the Central Slice theorem.¹¹ If the incremental angle between views is fine enough, the k -space distribution will be adequately sampled and the object can be reconstructed.

Thus, k -space is covered in a radial fashion for PR, as contrasted with the rectilinear coverage obtained in 2D FT methods. The consequences of this will be examined below in conjunction with the discussions of motion artifacts and S/N efficiency.

2.2 Projection–Reconstruction in MRI

Consider the 2D PR pulse sequence in Figure 2 which uses a selective excitation pulse requiring no refocusing.⁶ Projection data are collected at an angle θ during the simultaneous application of x and y gradients with amplitudes $G_{x0} = G_0 \cos \theta$, $G_{y0} = G_0 \sin \theta$, respectively. The signal is given by

$$S(t) = \int e^{i\gamma \int_0^t \mathbf{G}(t') \cdot \mathbf{r} dt'} m(x, y) dx dy \quad (6)$$

where $\mathbf{G}$ and $\mathbf{r}$ denote vectors with components (G_x, G_y) and (x, y) , respectively. Define

$$\left. \begin{aligned} k_x(t) &\equiv \gamma \int_0^t G_x(t') dt' \\ k_y(t) &\equiv \gamma \int_0^t G_y(t') dt' \end{aligned} \right\} \quad (7)$$

then

$$\gamma \int_0^t \mathbf{G}(t') \cdot \mathbf{r} dt' = k_x x + k_y y \quad (8)$$

so equation (6) becomes

$$S(t) = \int_{-k_{\max}}^{k_{\max}} \int_{-k_{\max}}^{k_{\max}} e^{i(k_x(t)x + k_y(t)y)} m(x, y) dx dy \quad (9)$$

Thus the signal corresponds to a two-dimensional FT of the object's distribution, sampled along the k -space trajectory $\mathbf{k}(t) = (k_x(t), k_y(t))$ defined by equation (7). This trajectory is shown as a radial line in Figure 1(b). Note that samples begin at the center of k -space, and that the 'echo time' (defined as the time at which the center of k -space is sampled) can thereby, in principle, be made arbitrarily small.

Figure 2 Pulse sequence for PR acquisition of one radial line in k -space starting at $k = 0$ (origin). Minimal echo delay is obtained using a self refocused rf pulse, which requires averaging of the signals from two excitations with inverted polarity of G_{slice} . The readout gradient is derived from vectorial combination of two or three gradients. If a k -space diameter is to be collected, a dephasing gradient pulse (not shown) is needed before readout, which lengthens the echo delay time

2.3 Resolution and Sampling Considerations

The pixel size and field-of-view (FOV) in an image reconstructed by Fourier transformation from data sampled in a Cartesian k -space matrix are determined by the extent and granularity of the sampling. For inversion of an $N \times N$ matrix, the pixel size p is related to the extent of coverage, measured by $\pm k_{\max}$ in Figure 3, as

$$p = \pi/k_{\max} \quad (10)$$

while the FOV, D , is given by

$$D = 2\pi/\Delta k \quad (11)$$

where $\Delta k = 2k_{\max}/N$ is the spacing between Cartesian samples.

Now suppose the k -space data are obtained by PR acquisition with each projection recorded as N_s uniformly spaced samples along a path starting at $\mathbf{k} = 0$, with a radius $k_{\max}$, as shown in Figure 3. The data may be interpolated onto the Cartesian grid with no loss of information if the spacing between the grid lines Δk is equal to the radial spacing between samples in the projection, $\Delta k_s = k_{\max}/N_s$, and the number of projections N_{views} is chosen so that the increment between angles $\Delta\theta$ satisfies

$$\Delta\theta k_{\max} = \Delta k = 2k_{\max}/N \quad (12)$$

Under these conditions, the Cartesian sampling will just match the radial sampling intervals at the periphery where $k = k_{\max}$, and will be oversampled for $|k| < k_{\max}$. This occurs when $N_{\text{views}} = \pi N$. If the signal sampling duration is T_{ad} , the gradient strength required for all imaging axes is given by

Figure 3 2D interpolation algorithms resample PR data onto a square output grid with a spacing Δk and a size $2k_{\max} \times 2k_{\max}$ for Fourier inversion. With gridding methods, each input measurement contributes to nearby output grid elements according to a kernel the values of which decrease with distance from the input point

$$k_{\max} = \gamma \int_0^{T_{\text{ad}}} G(t') dt' \quad (13)$$

$$= \gamma G_0 (T_{\text{ad}} - T_r/2) \quad (14)$$

for the ramped gradient in Figure 2.

The preceding development has assumed that the data are collected as radii. If diameters are to be collected (using a pulse sequence with a dephasing gradient before the readout), appropriate changes must be made, e.g., $N_{\text{views}} = (\pi/2)N$. In addition, k -space symmetry can be used if the object is real to halve the minimum number of views required since $M_{\theta+\pi}(k) = M_{\theta}^*(k)$ [from equation (3) and Brooks and Di Chiro¹²]. This may have certain advantages from the standpoint of motion; however off-resonance causes phase shifts whose effects may be reduced by the full view acquisition. The rest of this development assumes that conjugate symmetry is not used.

2.4 Signal-to-Noise Ratio (S/N)

The S/N is a complex function depending on the polarizability of the nuclei, Larmor frequency, coil efficiency, T_1 and T_2 relaxation weighting, and k -space sampling considerations. In this section we will only consider the impact of the k -space trajectory on the S/N value, and compare PR and FT methods. The measured signal for a view or projection is

$$y(t) = S(t) + n(t) \quad (15)$$

where $S(t)$ is the signal given by equation (9) and $n(t)$ is assumed to be white noise (over $|k| \leq k_{\max}$). We need only consider a reconstructed image of the signal and noise for a point object, and accordingly let $m(x, y) = m_0 \delta(x) \delta(y)$. Then using equations (19) and (20) below, one can show that the image intensity I and variance σ^2 at the origin for 2D FT and radial-sampled 2D PR are given by^{13,14}

$$\left. \begin{aligned} I_{\text{FT}} &= 4m_0 k_{\max}^2 \\ \sigma_{\text{FT}}^2 &= 2\sigma_0^2 k_{\max}^3 / N_y \end{aligned} \right\} \quad (16)$$

and

$$\left. \begin{aligned} I_{\text{PR}} &= \pi m_0 k_{\max}^2 \\ \sigma_{\text{PR}}^2 &= 4\pi^2 \sigma_0^2 k_{\max}^3 / 3N_{\text{views}} \end{aligned} \right\} \quad (17)$$

where N_y is the number of phase-encoding views for the 2D FT acquisition, σ_0^2 is the variance of the noise in a view or projection, and constant factors have been dropped for convenience. Letting $S/N = I/\sigma$ for each method,

$$\frac{S/N(\text{PR})}{S/N(\text{FT})} \equiv R = \sqrt{3N_{\text{views}}/8N_y} \quad (18)$$

If $N_y = N$ and $N_{\text{views}} = \pi N$ (i.e., minimum sampling requirement), $R = \sqrt{3\pi/8} \approx 1.08$. Thus, the radial PR technique takes π times longer to scan for the same resolution, but provides a slight S/N advantage. However, the efficiency disadvantage of PR is apparent if the S/N is calculated for constant scan time (using more averaging for the FT case than the minimum), and one finds that in this case $R = \sqrt{3/8} \approx 0.61$. However, this disadvantage is

often offset by the gain in motion immunity afforded by the redundant low-frequency sampling.

3 PULSE SEQUENCE CONSIDERATIONS

3.1 Radiofrequency Pulse

One of the motivations for using PR is to image materials with short T_2 values. In this case, it is desirable to minimize the time between the end of the excitation pulse and the beginning of the readout. In the case of 3D imaging, a short nonselective excitation pulse may be employed,⁵ while for 2D applications, three approaches are available. The first is to precede a short nonselective excitation pulse with a spatially-selective saturation pulse which leaves only the desired slice plane unperturbed.¹⁵ The second is to use a selective pulse that requires no refocusing, i.e., ends with the transverse magnetization in phase. This may be accomplished using half pulses which require two excitations/view, where each excitation scans half of the excitation k -space.⁶ The sequence in Figure 2 shows an example of the use of this kind of pulse. The third approach is the use of self-refocused spin echo pulses. Such pulses incorporate both a 90° and a 180° pulse in one composite envelope and produce an rf refocused echo at a specifiable time after the end of the pulse. This time can be made coincident with the end of the pulse for short T_2 imaging, and although the echo time cannot be made zero, there may be advantages for ultrashort rf-refocused echoes over gradient-recalled echoes.¹⁶

3.2 Field-of-View Considerations

In PR, it is important that all projections contain the entire cross-section of the subject without aliasing to avoid artifacts. In axial slices this is accomplished by making the FOV big enough; however, in sagittal or coronal orientations this may not be feasible for whole torso applications, because views with rays parallel to the magnet axis may include only part of the spins contained in views perpendicular to the axis. One technique to minimize deleterious effects which arise from such inconsistencies is to use rf coils (surface or volume) with a suitably limited sensitive region. A second approach is to use multidimensional excitation or saturation pulses to define only an inner volume of interest¹⁷ which can be wholly contained in the FOV.

4 RECONSTRUCTION TECHNIQUES

The PR image reconstruction is performed conceptually by inverting the FT of the k -space data. From equation (4), the image is given by the FT of the measured signal $M(k_x, k_y)$:

$$I(x, y) = \int M(k_x, k_y) e^{-i(k_x x + k_y y)} dk_x dk_y \quad (19)$$

Transferring to cylindrical coordinates in both image space and k -space and using equation (3),

$$I(\rho, \phi) = \int_{\theta}^{2\pi} d\theta \int_0^{k_{\max}} \hat{M}_\theta(k) e^{-ik\rho \cos(\theta-\phi)} k dk \quad (20)$$

Here the radially sampled projection data $M_\theta(k)$ are related to the measured signal $S(t)$ by a coordinate transform between time t and k -space radius from the origin, given by equation (7).

There are two general methods for implementing equation (20). The first is filtered back projection.¹¹ This technique is widely used for X-ray CT because it allows convenient incorporation of source-to-detector intensity factors for the divergent-ray geometries commonly employed, and much has been written about this broad class of methods in the CT context. In fact, the early NMR imaging experiments used this approach,¹ and the relative merits of back projecting magnitude versus complex amplitude projections have been debated.^{9,18} However, back projection reconstruction has not been used as much for MR applications as the second method, which uses interpolation of the raw data onto a rectangular matrix for FT inversion.

Interpolation methods can use a variety of techniques to resample the radially gathered raw data into elements of a Cartesian output matrix, following which a 2D or 3D FT inversion is performed to create the image(s). Interpolation algorithms can use bi/tri-linear or higher order methods, where each output datum is calculated from a suitable combination of nearby k -space input data.¹¹ Alternatively, a gridding technique can be employed for greater effectiveness.¹⁹ In gridding, each input datum is multiplied by elements of a multidimensional filter and the results summed into all nearby output grid points according to the prescribed kernel weighting, which varies according to the distance of the output point from the input point. The fractional contribution that each output element receives is recorded and used to normalize the sampling density. This correction automatically accounts for the oversampling at the origin of k -space ($|k|$ or $|k|^2$ weighting for 2D or 3D acquisitions, respectively), as well as for nonuniform sampling of the projection data during gradient ramp-up.

5 ARTIFACTS IN PROJECTION–RECONSTRUCTION

5.1 Motion Effects

The motion of structures causes artifacts in conventional FT imaging. The artifacts appear either as ghosts or streaks, displaced in the phase-encoding direction, and can be accompanied by blurring of the moving structures. (See *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control; Whole Body Magnetic Resonance Artifacts*.)

Projection–reconstruction methods, in addition to allowing negligible delay time before the collection of data, often have superior motion characteristics because of two mechanisms.⁹ The first mechanism is that the low spatial frequencies are heavily oversampled, since each projection either starts at, or crosses through, $k = 0$. This provides an intrinsic averaging of

the spectral components which contribute most of the signal power to the image, and therefore motion artifacts are substantially attenuated. The second mechanism is that motion artifacts are manifested with PR as streaks emanating from the moving structures, rather than as ghosts. The streaks tend to lie along rays perpendicular to the displacement direction. In abdominal scans, for example, the motion of the abdominal wall causes horizontal streaks which lie largely outside the torso in the image. Moreover, streaks from quasiperiodic motion are often not evident close to the moving structure, but become apparent only at some distance in the image. This occurs because of diffraction between adjacent streaks which causes cancellation of the inconsistent energy close to the moving structures.

Despite the relative immunity of PR methods to motion, inconsistencies remain which cause streak artifacts. One method of reducing artifacts further is the use of an algorithm which prospectively chooses the view angles depending on the motion (Retrospective Ordered View Angulation, or ROVA).⁹ In axial abdominal scans this occurs, for example, by requiring the projection rays to be aligned with the anterior–posterior direction of the patient during peak inspiration, when the respiratory motion is most rapidly evolving. A second method uses consistent projection–reconstruction (CPR) algorithms, which create a set of raw data from the scan data that is consistent with a stationary object.²⁰ The resulting reconstruction shows diminished streaks, although the blurring remains.

Thus, PR methods often have smaller artifacts from mis-placed signal energy than FT methods, but motion nevertheless causes blurring of the moving structures as in FT methods. Usually blurring is less deleterious than the overlaid ghosting, and PR is therefore more robust in the presence of physiological motion.

5.2 Off-resonance Effects

Chemical shift or field heterogeneity can cause off-resonance effects during acquisition. With FT methods, this results in a spatial shift of the depicted structures along the readout direction. In PR methods, the result is blurring. This may be easily demonstrated by calculating the reconstruction of a point at the origin, for projections acquired as radii. The effect of a loss of resonance is to shift every projection by an amount $\delta r = \delta\omega / \gamma G_0$ dependent on the offset frequency $\delta\omega$ and the readout gradient amplitude. For a point object, the FT of the offset-shifted projection is given by $M_\theta(k) = \exp(ik\delta r)$. The reconstruction will be cylindrically symmetric, and equation (20) becomes

$$I(\rho) = \left\{ \begin{aligned} &\int_{\theta}^{2\pi} d\theta \int_0^{k_{\max}} e^{ik\delta r} e^{-ik\rho \cos\theta} k dk \\ &= \begin{cases} 2\pi\delta r((\delta r)^2 - \rho^2)^{-3/2} & (\rho < \delta r) \\ i2\pi\delta r(\rho^2 - (\delta r)^2)^{-3/2} & (\rho > \delta r) \end{cases} \end{aligned} \right\} \quad (21)$$

It may be seen that the point object has been reconstructed with its intensity peaked sharply at a circle with radius equal to the offset δr , and the point has thus been blurred.

Off-resonance therefore causes a loss of resolution in non-Cartesian methods such as PR. If the offset is spatially uni-

form, a simple phase correction to the data will remove the blurring. However, if the offset is spatially variant but the distribution is known from a field heterogeneity map, regional corrections can be applied by reconstructing the image at resonance offsets appropriate to each region of the imaging volume and piecing the image together. The field map can be obtained by separate acquisitions or by inference from a regional blurring cost function such as minimizing the imaginary component of the image.²¹

6 SPIRAL TECHNIQUES

The PR methods have advantages with respect to motion robustness and short T_2 imaging. However, the number of views needed to obtain a specified resolution is about 1.5–3 times greater than that for a 2D FT method. One related alternative that has the advantages of PR but is more efficient is spiral k -space trajectory acquisitions.²² The acquisition begins radially at $k = 0$, but quickly becomes predominantly azimuthal and is therefore more efficient because there is less redundant sampling of the low-spatial frequencies, and the gradients can be operated at the maximum value for most of the readout duration. An added advantage of these trajectories is that the gradient moments start at zero, and periodically return to zero, which provides intrinsic moment compensation for additional motion insensitivity. (See *Spiral Scanning Imaging Techniques*.)

7 APPLICATIONS AND EXAMPLES

Figure 4 illustrates the use of 2D PR for imaging lung parenchyma, and compares the results with an image obtained in the same scan time using a conventional 2D FT method. In this application, both the immunity from motion artifacts and the short effective echo time are a significant advantage for PR.²³ A comparison of PR and FT for abdominal scanning is shown in Figure 5. Again the advantage of PR in the presence of respiratory motion is clear. Another application for PR is in diffusion weighted imaging, where flow artifacts are especially severe with FT imaging but are minimal with PR.¹⁸

Other applications for PR utilize the short echo time, and include imaging of ^{23}Na , for which the intracellular compartment has a transverse relaxation component with $T_2 < 10$ ms, ^{11}B with $T_2 < 1$ ms for boron neutron capture therapy, and lipid components in atherosclerotic plaque.²⁴

In BOLD-contrast brain activation imaging²⁵ with conventional FT techniques, subtle motion of the brain from vasculature can cause artifacts which mask the relatively weak activation signal. This has driven the use of echo planar methods,²⁶ but these ‘snapshot’ acquisitions suffer from limited spatial resolution. Projection–reconstruction and spiral acquisitions have been found to be highly effective for this application, using conventional MR scanners.²⁷ (See *Echo-Planar Imaging*.)

Figure 4 Images gathered at 1.5T with PR ($TE = 0.25$ ms) and spin echo 2D FT ($TE = 20$ ms), using the same total scan time. Respiratory motion and short T_2^* (<8 ms) causes poor visualization of lung parenchyma with the conventional method

Figure 5 Comparison of T_1 -weighted spin echo images with a conventional 2D FT technique (a, c) and PR technique (b, d). Scan time and TE were the same. Fat saturation was applied in the PR scans to reduce the effect of off-resonance

Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control

Pradip M. Pattany

University of Miami, Miami, FL, USA

1 INTRODUCTION

The most common method used for MR imaging is 2D FT imaging; in this method, the frequency and phase of the spin within a given slice determines its spatial location along the frequency and phase-encoding directions. However, the standard 2D FT imaging technique does not take into account the effects of motion and flow. It has been shown that in 2D FT imaging, motion and flow occurring in any direction result in inappropriate distribution of the signal (i.e., artifacts) in the phase-encoding direction.^{1,2} The majority of artifacts in clinical imaging are due to physiologic motion and to flow.

The most frequently encountered types of physiologic motion are respiratory and cardiac. These motions are periodic; hence, they can be monitored and the data acquisition can be synchronized to occur when motions are at a minimum. This is the approach used in gating methods³ (see also *Cardiac Gating Practice*) to suppress motion artifacts. In these methods, motion occurring between data acquisition and the following 90° excitation pulse (known as view-to-view motion) is taken into consideration. There is a considerable time penalty associated with respiratory gating (see *Motion Artifacts: Mechanism and Control*); however, this has been overcome by the use of the ROPE⁴ (respiratory ordered phase encoding) technique, which orders the phase-encoding steps in a way that motion appears to execute a monotonic progression over the complete image acquisition.

Another approach to the reduction of artifacts due to flow or motion is to obtain several acquisitions for each phase-encoding step. This averages out the differences in accumulated phase due to flow and motion, thus reducing the artifacts. This method is called signal averaging. As data acquisition methods are becoming shorter, to the point where data can be obtained in hundreds of milliseconds, one could suspend motion during the data acquisition (in particular, respiratory motion). This is known as the breath-hold method.⁵

There are other types of physiologic motions that are not periodic, such as peristaltic, swallowing, tongue, and rapid eye motions. All these motions are involuntary and random in nature. While peristaltic motion can be controlled by glucagon, the duration of action of the drug is short compared with the total scan time. Therefore, glucagon has not proved useful for motion artifact reduction. In order to eliminate artifacts generated by all types of physiologic motions, one needs to use a different approach.

Most of the methods used for suppression of motion artifacts fail to consider the interaction of moving spins with the pulsed imaging gradients. The motion occurring between the 90° excitation pulse and data acquisition (known as within-view motion) can lead to accumulation of phase, which results in artifacts along the phase-encoding direction. When spins are moving in time, the gradients they experience change with time owing to the changes in their spatial positions. The rate at which the changes in gradients are observed depends on the direction of motion and the speed of the moving spins. In order to minimize the accumulation of added phase due to motion, additional pulses are applied to standard 2D FT imaging gradients. This is accomplished by expanding the motion as a power series in terms of position, velocity, acceleration, and pulsatility (higher-order terms), and incorporating these terms into the design of the imaging gradient.

2 THEORY

Any within-view motion or flow occurring along the frequency-encoding gradient and the slice selection gradient direction between the 90° rf pulse and data collection leads to incomplete rephasing of the moving spins at the center of the data collection in the standard frequency-encoding gradient, and at the end of the slice selection gradient. This added random phase term in 2D FT MR imaging leads to signal loss and to artifacting in the phase-encoding direction.⁶

The motion or flow occurring in the phase-encoding direction does not lead to signal loss and artifacting, because the length of time for which the phase encode is applied is very small compared with the frequency-encoding and slice selection gradients. Thus, the random phase accumulated over that time period is minimal. Secondly, the maximum signal occurs near the central phase-encoding views. Thus, the expected artifacts due to motion would be high in signal intensity. However, the amplitude of the phase-encoding gradient is close to zero. Therefore, there is little or no artifacting associated with flow or motion in the phase-encoding direction. The excited signal in the transverse plane is expressed in equation (1a), where it is clearly seen that the signal would indeed be affected by the phase of the excited spins in the transverse plane:

$$S(t_x, t_y) = \iint \bar{\rho}(x, y) e^{-i2\pi(\phi_x(t_x) + \phi_y(t_y))} dx dy \quad (1a)$$

where $S(t_x, t_y)$ is the signal in the (x, y) transverse plane, $\bar{\rho}(x, y)$ is the spin density in the transverse plane, $\phi_x(t_x)$ and $\phi_y(t_y)$ are the phases at times t_x and t_y , and

$$\bar{\rho}(x, y) = \int \bar{\rho}(x, y, z) e^{-i2\pi\phi_z(t_z)} dz \quad (1b)$$

$$\bar{\rho}(x, y, z) = \rho(x, y, z) (1 - e^{-TR(x, y, z)/T_1}) \quad (1c)$$

Partial volume effects due to finite slice thickness are contained within $\bar{\rho}(x, y)$ as a result of integration along dz .

In order to obtain maximum signal at the echo time in the transverse (x, y) plane following a selective 90° rf pulse, the exponential term in equation (1b) must be equal to one:

$$e^{-i2\pi\phi_z(t_z)} = 1 \quad (2)$$

This occurs when $\phi_z(t_z)=0$, which implies that the spins in the transverse plane are completely rephased at the echo time. The phase term $\phi_z(t_z)$ in equation (2) can be expressed as

$$\phi_z(t_z) = \gamma \int \bar{G}_z(t_z) Z(t_z) dt_z \quad (3)$$

where $\phi_z(t_z)$ is the phase of the magnetization at time t_z , γ is the magnetogyric ratio, $\bar{G}_z(t_z)$ is the gradient amplitude at time t , and $Z(t_z)$ is the position of the excited spins at time t . The position term $Z(t_z)$ can be expanded in a Taylor series:

$$Z(t_z) = Z_0 + \sum_{j=1}^{\infty} \frac{t_z^j Z_0^{(j)}}{j!} \quad (4)$$

where $Z_0^{(j)}$ is the j th derivative of Z_0 .

Each of the terms of the expanded $Z(t_z)$ expression in equation (4) is integrated separately in equation (3), and the phase ϕ_z associated with each term is brought to zero at the end of the slice selection gradient waveform. A similar expression for the frequency-encoding gradient requires that the phase be brought to zero at the center of the data collection gradient lobe. When the term $Z_0^{(j)}$ in equation (4) is expanded up to its third derivative, the term $Z(t_z)$ can be expressed as

$$Z(t_z) = Z_0 + \frac{t_z}{1!} \frac{dz}{dt} + \frac{t_z^2}{2!} \frac{d^2z}{dt^2} + \frac{t_z^3}{3!} \frac{d^3z}{dt^3} \quad (5)$$

On the right-hand side, the first term Z_0 for static spins is of zeroth-order (zeroth moment). The second term dz/dt is for the spins moving with constant velocity, and is of first order (first moment). The third term d^2z/dt^2 is for the spins moving with constant acceleration, and is of second order (second moment). The fourth term d^3z/dt^3 is for the spins moving with pulsatility, and is of third order (third moment).

Equation (5) can be substituted into equation (3), which now becomes

$$\phi_z(t_z) = \gamma \int \bar{G}_z(t_z) \left(Z_0 + \frac{t_z}{1!} \frac{dz}{dt} + \frac{t_z^2}{2!} \frac{d^2z}{dt^2} + \frac{t_z^3}{3!} \frac{d^3z}{dt^3} \right) dt_z \quad (6)$$

For complete rephasing of the moving spins (velocity, acceleration and pulsatility) at the end of the slice selection gradient, and at the center of data sampling for the frequency-encoding gradient, each of the Z terms in equation (6) must be integrated separately, and the $\phi_z(t_z)$ term has to be equated to zero for a given gradient waveform. This can be expressed as a set of equations for the $\phi_z(t_z)$ phase associated with each order of $Z(t_z)$ as follows:

$$\phi_z(t_z) = \gamma \int \bar{G}_z(t_z) dt_z = C_0 = 0 \quad (7a)$$

$$\phi_z(t_z) = \gamma \int \bar{G}_z(t_z) \frac{t_z}{1!} dt_z = C_1 = 0 \quad (7b)$$

$$\phi_z(t_z) = \gamma \int \bar{G}_z(t_z) \frac{t_z^2}{2!} dt_z = C_2 = 0 \quad (7c)$$

$$\phi_z(t_z) = \gamma \int \bar{G}_z(t_z) \frac{t_z^3}{3!} dt_z = C_3 = 0 \quad (7d)$$

$$\phi_z(t_z) = \gamma \int \bar{G}_z(t_z) \frac{t_z^j}{j!} dt_z = C_j = 0 \quad (7e)$$

This set of equations can be expressed in terms of a matrix equation

$$\{t^j\}\{G^j\} = \left\{ \frac{\phi}{Z_0^j \gamma} \right\} - \left\{ \sum_k G^k \right\} \quad (8)$$

where $\{t^j\}$ are the specified times of the unknown gradient lobes, expressed as a $j \times j$ matrix, $\{G^j\}$ are the amplitudes of the unknown gradient lobes that are to be calculated, expressed as a $j \times 1$ matrix, $\{\phi/Z_0^j \gamma\}$ are the desired phases of the spins divided by the derivative of Z_0 and the magnetogyric ratio, expressed as a $j \times 1$ matrix, and $\{\sum_k G^k\}$ is the summation of the known gradient lobes with amplitude and times specified (e.g., the gradient lobes applied during the 90° and 180° rf pulses to give a correct slice thickness), expressed as a $j \times 1$ matrix.

Each gradient lobe in a given gradient waveform has finite rise and fall times. Therefore, each gradient lobe is a trapezoidal profile, rather than the rectangular profile assumed in equation (8). This leads to the accumulation of random phase during rise and fall times, owing to motion or flow, particularly in the higher order terms (acceleration and pulsatility), because the term t_z in the integrals in equations (7c) and (7d) is t^2 and t^3 , respectively. The rise and fall times of the trapezoid can be approximated as a series of contiguous short-duration rectangular pulses, of increasing amplitude on the rising ramp of the trapezoid, and decreasing amplitude on the falling ramp. With the inclusion of rise and fall ramps, the phase term $\phi_z(t_z)$ in equation (3) now becomes

$$\begin{aligned} \phi_z(t_z) = & \sum_{i=1}^{\eta_r} \int_{t_1+(i-1)t_r/\eta_r}^{t_1+i t_r/\eta_r} \gamma G_r(t_z) Z(t_z) dt_z \\ & + \int_{t_1+t_r}^{t_2-t_f} \gamma G_z(t_z) Z(t_z) dt_z \\ & + \sum_{i=\eta_f-1}^0 \int_{t_2-(i-1)t_f/\eta_f}^{t_2-i t_f/\eta_f} \gamma G_f(t_z) Z(t_z) dt_z \end{aligned} \quad (9)$$

where η_r is the number of steps for the rising ramp, η_f is the number of steps for the falling ramp, t_1 is the starting time of the trapezoid, $t_1 + t_r$ is the end of the rising ramp and the beginning of the plateau or constant section, $t_2 - t_f$ is the end of the plateau or constant section and the beginning of the falling ramp, t_2 is the end of the falling ramp, t_r is the total time of the rising ramp, and t_f is the total time of the falling ramp. Equation (9) is shown diagrammatically in Figure 1.

When the gradient profiles are generated using equation (9), the numbers of steps η_r and η_f are defined to be very large for given t_r and t_f . Thus, the rising and falling ramps could be con-

Figure 1 Trapezoidal waveform for each gradient pulse in a given gradient waveform

sidered as linear ramps, rather than discrete steps of rectangles, increasing or decreasing in amplitude. In equation (9), one can see that the first term corresponds to the integral summation of the rising ramp. The second term corresponds to the integral of the plateau, or constant section of the trapezoid. The third term corresponds to the integral summation of the falling ramp. Therefore, equation (9) is the one that is used in the matrix in equation (8).

The values of the $\{t^j\}$, $\{\phi/Z_0^j\gamma\}$, and $\{\sum_k G^k\}$ terms in equation (8) are specified for a given gradient waveform. The $\{G^j\}$ term, for amplitude values of the unknown j gradient lobes, can be calculated by solving the $j \times j$ matrix $\{t^j\}$ in terms of the specified times, and dividing it into either side of equation (8), which now becomes

$$\{t^j\}^{-1} \{t^j\} \{G^j\} = \left(\left\{ \frac{\phi}{Z_0^j \gamma} \right\} - \left\{ \sum_k G^k \right\} \right) \{t^j\}^{-1} \quad (10)$$

$$\{G^j\} = \left(\left\{ \frac{\phi}{Z_0^j \gamma} \right\} - \left\{ \sum_k G^k \right\} \right) \{t^j\}^{-1} \quad (11)$$

All the terms on the right-hand side are known, and therefore the amplitude values for G can be calculated for j unknown gradient lobes. The resultant waveform will rephase the $(j-1)$ th order of motion.

3 GRADIENT WAVEFORM PATTERNS

To rephase completely the moving spins in the slice selection and frequency-encoding directions, the standard spin echo imaging sequence shown in Figure 2 (see *Spin Warp Data Acquisition*) is modified for within-view motion correction as shown in Figure 3. To rephase terms of zeroth-order (static) through to third order (pulsatility) in the slice selection gradient waveform, four unknown (A, B, C, D) gradient lobes are applied at specified time intervals in a slice selection gradient waveform. The time zero, $t_0=0$, is considered to be the center of the 90° rf pulse, as is the case when refocusing the static spins in conventional imaging sequences.

The amplitude and the times of the slice selection lobes, applied during 90° and 180° rf pulses (denoted by the solid lines in Figure 3), must be known in order to give a correct slice thickness and echo time. Therefore the gradient lobes with known amplitude and times are included in the $\{\sum_k G^k\}$

Figure 2 A standard 2D FT spin echo imaging sequence

terms in equation (8). If all the terms from zeroth-order through to third order are completely refocused at time t_6 then the term $\{\phi/Z_0^j\gamma\}$ is equal to zero. The term $\{t^j\}$ in the equation includes all the specified time values ($t_1, t_2, t_3, t_4, t_5, t_6$), of the unknown gradient lobes. Therefore a 4×4 matrix $\{t^j\}$ is solved in terms of the specified time intervals. It is then inverted and multiplied into both sides of equation (8), which now becomes equation (10). For simplification, put

$$\left\{ \frac{\phi}{Z_0^j \gamma} \right\} - \left\{ \sum_k G^k \right\} = \{K^j\} \quad (12)$$

Then equation (10) can be written as

$$\{G^j\} = \{K^j\} \{t^j\}^{-1} \quad (13)$$

All the known values are on the right-hand side of equation (13). Therefore, the $\{G^j\}$ term can be solved for the amplitudes of the unknown gradient lobes (A,B,C,D) in the slice selection gradient waveform by multiplying the matrix $\{K^j\}$ by the matrix $\{t^j\}^{-1}$.

Similarly, the method can be applied to the frequency-encoding gradient waveform, since the time and the amplitude of the data collection gradient lobe (denoted by a solid line in Figure 3) is known. Four unknown gradient lobes (a, b, c, d)

Figure 3 A 2D FT spin echo imaging sequence with motion compensation up to pulsatility applied to the slice selection and frequency-encoding gradients

are applied to the frequency-encoding gradient, as shown in Figure 3. The data collection gradient lobe is the term $\{G^k\}$, in which the amplitude and the times must be known in order to give a correct echo time and field of view. The term $\{\phi/Z_0^j\gamma\}$ is specified to be zero, if all the terms from zeroth-order through to third order are to be completely rephased at the echo time. The term $\{t^j\}$ gives the times (t_1, t_2, t_3, t_4, t_5) of the unknown gradient lobes, which are specified as in Figure 3.

Again, a 4×4 matrix $\{t^j\}$ is solved, inverted, and multiplied by $\{K^j\}$ as in equation (13) to determine the amplitudes of the a, b, c, and d pulses, which result in complete rephasing of the static through to the pulsatile spins moving in the frequency-encoding direction.

4 TYPICAL PERFORMANCE

A set of images were obtained on a volunteer, with a 1.5 T whole body MRI system. A quadrature body coil was used for excitation and a quadrature lumbar spine coil as a receiver. A standard spin echo sequence and a modified sequence (within-view motion compensation up to pulsatility in frequency-encoding and slice selection gradient direction) were run consecutively with the following scan parameters: echo time of 100ms, repetition time of 2000ms, 2 acquisitions per phase-encoding step, 256 phase-encoding steps, and a 27 cm field-of-view. Both images were acquired without using cardiac and/or respiratory gating devices.

The set of images shown in Figures 4 and 5 were acquired from the lumbar spine region. As can be seen in Figure 4, there is noticeable signal loss and artifacting across the image. This is due to cerebrospinal fluid (CSF) flow and peristaltic motion of the intestine. The presence of these artifacts degrades image quality and obscures delineation of the spinal cord and the nerve roots in the spinal canal, and the anatomical structures

Figure 4 Image of lumbar spine acquired with a standard 2D FT spin echo imaging sequence

Figure 5 Image of lumbar spine acquired using a 2D FT sequence with motion compensation up to pulsatility applied to the slice selection and frequency-encoding gradients

anterior to the vertebral body are completely obscured by the artifacts.

In Figure 5, the artifacts due to peristaltic motion and CSF flow are eliminated. Visualization of the structures within the abdomen anterior to the spine is improved. Also, the spinal cord and nerve roots are now well delineated against the bright signal from the CSF.

5 DISCUSSION

The proposed method for within-view correction of motion in the frequency-encoding and slice selection directions completely rephases the signal from the moving spins with velocity, acceleration, and pulsatility. For within-view motion, the relative significance of motion of the imaging axes and the effects of spins moving during application of NMR imaging gradients has been assessed.⁶ Dephasing due to motion and flow occurring along the slice selection, frequency-encoding, and phase-encoding directions has been investigated. A flow phantom under constant flow conditions was used in experiments to study the method. The within-view motion correction method was used to rephase signals along various combinations of imaging axes, applying variable terms from the Taylor expansion of motion along them. The results indicated that motion along any imaging axis can be rephased effectively when within-view motion correction is used only along the slice selection and frequency-encoding directions.

The improvement in image quality in the areas of head, abdomen, chest, and spine was assessed on patients using the within-view motion correction method.⁷ There is an increase in signal intensity and anatomical details in the presence of flow and motion. The technique reduced the practical difficulty of obtaining clinically diagnostic T_2 weighted images in a reasonable acquisition time without having to perform multiple signal

averaging. It has also been shown that signal loss and the resulting artifacts due to flow, orbit, tongue, swallowing, peristaltic, and respiratory motions are eliminated, and that this method is also applicable to other 2D FT imaging sequences.^{7,8}

The image quality assessment has been extended to various sequences on a larger patient population.⁹ There was considerable improvement in image quality: the CSF flow artifacts were eliminated, and body and spine images had reduced blood flow and motion artifacts. The blood vessels gave an increased signal, which would be useful in cardiovascular imaging.

The within-view motion correction method has been used on patients at 0.5 and 1.5 T field strengths,¹⁰ and it has been found that there is a more significant reduction in motion and flow artifacts than that achieved by even echo rephasing alone.¹¹

The most commonly used gradient waveforms are composed of trapezoidal or sinusoidal pulses. However, given hardware constraints and the sequence parameter objectives, one could use a numerical approach to gradient waveform design. It has been shown that the amplitude of the gradient pulses can be calculated on a point-to-point basis to achieve within-view motion correction.¹²

Theoretically, solving for terms of increasingly higher order will continue to reduce the degree of signal loss and artifacting, providing the higher order terms are dominant in the moving anatomical regions. From clinical evaluation, higher order terms (higher than pulsatility) have negligible, if any, effect on image quality.

Selective Excitation in MRI and MR Spectroscopy

Andrew A. Maudsley and Gerald B. Matson

University of California San Francisco and VA Medical Center, San Francisco, CA, USA

1 INTRODUCTION

With the continuous wave methods used in the early days of NMR, the ability selectively to excite specific frequencies was inherently available, and the ideas of selective excitation were widely used to elucidate spin and dipolar couplings and multiple quantum transitions.^{1,2} The advent of Fourier transform (FT) NMR provided for simultaneous excitation over a broad frequency span and yielded greatly improved sensitivity, but complicated the process of selective excitation of spins. This nonselectivity of the FT NMR excitation methods brought the need for solvent suppression into prominence for high-resolution studies, and the application of NMR to ever increasingly more complicated spin systems has spawned a variety of selective excitation methods designed for spectral simplification to enhance identification of individual spin systems.³

For FT NMR, a broadband excitation of the spin system is readily provided by a short rf pulse. Excitation over only a limited frequency region can be obtained by lengthening the rf pulse such that the excitation profile is narrowed; however, this approach is limited since the excitation profile in the frequency domain is described by a sinc function rather than the ideal, trapezoidal shape depicted in Figure 1(a). Improved frequency excitation profiles can be obtained by suitable amplitude shaping of the rf pulse, or more generally by using a suite of closely spaced rf pulses with different parameters (amplitude, phase, frequency, intra- or inter-pulse intervals).

In modern high-resolution NMR, applications of selective excitation techniques include elucidation of spin couplings, measurement of dipolar couplings (i.e., nuclear Overhauser enhancements), exploration of multiple quantum coherences, and solvent suppression (see *Water Suppression in Proton MRS of Humans and Animals*), as well as spectral simplification. In the presence of a magnetic field gradient, frequency selective excitation is translated into spatially selective excitation. This is illustrated in Figure 1(b), where irradiation using the frequency profile shown in Figure 1(a), results in excitation of spins within a slice through the object [Figure 1(b)]. In this example the X gradient was applied resulting in excitation of a plane perpendicular to X (i.e., over the YZ plane). In this article we describe the development of frequency selective excitation methods for spatially selective excitation, which is required for MRI and for spatially resolved spectroscopy (see *Single Voxel Localized Proton NMR Spectroscopy of Human Brain In Vivo*). For these applications the usual requirement is for slice selection (i.e., excitation or inversion of spins within a region bounded by parallel planes). In the ideal case the excitation would be flat over some predefined region, with sharp tran-

sitions and zero excitation outside of that region, as illustrated in Figure 1(a).

2 BACKGROUND

Tomlinson and Hill⁴ introduced ideas of selective excitation for FT NMR using inverse FT of the frequency band to be excited as the basis for generating the pulse train producing the selective excitation. Limitations of this approach due to the nonlinearity of the Bloch equations were realized in this early work, and, because of phase dispersal of the transverse magnetization produced by their formalisms, the selective excitation was not proposed for direct observation of selectively excited spins. Instrumentation limitations of commercial FT NMR spectrometers restricted the utilization of the Tomlinson–Hill selective excitation approach and it was not until Morris and Freeman⁵ introduced the DANTE pulse scheme that selective excitation became readily available on commercial FT NMR spectrometers. Although widely used, the DANTE scheme still produced a sinc-shaped excitation profile.

Early applications of selective excitation for spatial selection were demonstrated by Garraway et al.⁶ and Mansfield et al.⁷

Figure 1 (a) Ideal frequency selection or slice profile. The ideal frequency selective excitation pulse produces uniform excitation over the passband, and no excitation in the stopbands. In addition, in the ideal case the transition bands are narrow compared with the passband. (b) Depiction of the action of a frequency selective pulse in the presence of a magnetic field gradient. In the presence of a magnetic field gradient, frequency selection is translated into spatial selection, so that the frequency selection depicted in (a), in the presence of a magnetic field gradient in the X direction, excites the slice depicted in (b).

for line scan imaging. Here the selective rf pulse was applied together with a magnetic field gradient across the sample, thereby causing only those spins which resonated at the frequencies within the excitation band of the selective pulse to be affected, and the resultant spin excitation was limited to a well-defined region of the object [Figure 1(b)]. Negative amplitudes produced by the FT formalism were accommodated by 180° phase reversal of the rf pulse and the gradient was switched on prior to application of the rf pulse, and held constant during the pulse. This use of a linear magnetic field gradient, referred to as the slice-selection gradient, produced a direct relationship between the selected region and the excitation frequency. The thickness of the excited slice depended on the strength of the slice-selection gradient as well as the frequency range excited by the selective pulse. The quality of the slice selection was a function of the length and shape of the rf pulse.

The early imaging articles lacked specifics as to the action of selective pulses;^{7,8} however, it was later demonstrated by Hutchison et al.⁹ and Hoult¹⁰ that at the end of an excitation pulse the spins were excited with a spatially dependent phase, and that in order to recover the full magnetization it was necessary to reverse the applied gradient after the end of the pulse. The earlier formalism of Morris and Freeman⁵ also anticipated this result. More rigorous treatments of selective pulses using the Bloch equations followed,^{10,11} which showed that the integral of the refocusing gradient was approximately half that of the slice-selection gradient. These analyses also demonstrated that since the spin response to rf excitation is nonlinear, in the sense that the amount of transverse magnetization generated is not a linear function of amplitude of the applied rf, the FT methods for selective pulse generation were rigorous only in the limit of small tip angles. However, the errors in this approach do not become prohibitive until tip angles exceeding 90° are used, and sinc-shaped pulses, smoothed with a Gaussian (or other filter function) to reduce ringing effects, became commonly used in MRI and localized spectroscopy for 90° excitation of a slice through an object. Figure 2 shows a sinc-Gauss pulse shape [Figure 2(a)] and the resultant observed transverse magnetization across the selected slice [Figure 2(b)] following application of a 90° sinc-Gauss pulse together with the necessary refocusing gradient. It can be seen that significant magnetization is excited outside of the selected slice and the resultant phase after refocusing exhibits deviation from zero.

The selective pulses discussed above were, for the most part, amplitude modulated with phase reversal taking the place of negative rf amplitude. Selective excitation using frequency (or phase) modulation is also possible, and in the early 1980s two separate groups demonstrated similar formalisms for generation of inversion pulses with immunity to B_1 inhomogeneity.^{12–16} These inversion pulses were analogous to adiabatic fast passage in high-resolution NMR, and once a threshold value of the rf strength was exceeded, the inversion became virtually independent of rf power. The second of these pulses, the hyperbolic secant pulse,^{14–16} was shown to have reasonable frequency selectivity characteristics. Although the hyperbolic secant pulse was cast theoretically in terms of frequency and amplitude modulation, it could equivalently be implemented as an amplitude and phase modulated pulse.¹⁷

While the hyperbolic secant pulse had the advantage of being immune to rf inhomogeneity, it did not perform as a

Figure 2 (a) A sinc-shaped 90° excitation pulse with Gaussian apodization. The Figure shows a 128-step 90° pulse derived from a sinc shape with Gaussian apodization. (b) Resultant slice profile from the pulse of (a). The solid line shows the in-phase signal after gradient refocusing. Although the excitation is uniform over the passband, significant excitation is evident in the stopbands. The broken line shows the quadrature signal, which exhibits significant deviation from zero

180° refocusing pulse, and in the early 1980s the demands of MRI and localized spectroscopy created a clear need for large tip angle rf pulses (including spin echo pulses) with improved slice profiles, and pulses with immunity to rf inhomogeneity. The need for multidimensional pulses exciting, for instance, simultaneously in two directions, became apparent in the latter half of the 1980s, and this class of pulse is discussed near the end of this article.

3 AMPLITUDE MODULATED PULSES

3.1 Early RF Pulse Design

For slice selective pulses the ‘ideal’ selection profile is one which has a flat excitation over the slice, narrow transition regions, and minimal excitation outside of the slice (Figure 1).

Although early pulse shaping relied on the Fourier time–frequency relationship, as noted above this approach is not rigorous outside of the small tip angle regime. Subsequent work showed that amplitude modulation is sufficient for generation of excellent excitation profiles as long as the rf field is homogeneous.¹⁸ When significant rf inhomogeneity is present, it turns out that frequency modulated designs may be used with inversion or refocusing pulses to provide variable degrees of immunity to rf inhomogeneity,¹⁷ although a price in pulse length or excitation profile is inevitably required. This class of pulse is discussed in the next section. Finally, selective pulse generation always involves tradeoffs of overall pulse duration and, in some cases, pulse amplitude, and acceptable excitation profile. That is, increasing pulse duration may provide an improved selection profile, but lengthens the experiment and may incur profile degradation due to relaxation during the pulse.^{19–21} In addition, reducing the transition region at constant pulse duration invariably has its cost in increased deviations over the desired profile.

The difficulty of generating desired trapezoidal excitation bands was highlighted by theoretical analyses of selective pulse shapes^{10,11} developed prior to 1980, which pointed out that the Bloch equations are nonlinear. Thus, in general, the problem of finding the amplitude modulation that best approaches a desired excitation profile (for a given overall pulse duration) is nonlinear, and requires an iterative approach for solution.

A number of approaches to pulse optimization appeared in the middle 1980s. Silver et al.¹⁴ showed that the Bloch–Ricatti equation could be used as a basis for optimization of a 90° pulse. The work of Warren showed how pulse profiles could be improved starting with a particular class of pulse shape.²² The approach of Carlson²³ provided for improved excitation pulse profiles, while that of Adams and O’Donnell²⁴ provided for improved spin echo pulses. Using a simplex method, Lurie showed that sinc-shaped rf pulses could be reshaped to provide improved excitation, inversion, and spin echo pulses.²⁵

3.2 Optimal Control Theory

More general methods for pulse optimization were demonstrated in the optimal control theory approaches of Conolly et al.¹⁸ and Murdoch et al.¹⁷ which provided for optimization of excitation, inversion, and spin echo pulses. Both of these approaches used a penalty function for rf power so that, within the other pulse constraints, the optimization process produced the lowest power pulse. These approaches demonstrated that optimal control theory provided a robust, albeit time-consuming, approach to generation of amplitude modulated pulses.

The approach of Murdoch et al.¹⁷ is described with the aid of Figure 1(a), which here represents the target profile. An initial pulse shape was run through the Bloch equations, and the square of the deviation from the target profile function calculated, which represented the error or ‘cost’ parameter to be minimized. In the Murdoch formulation, deviations in the transition region were ignored, and other ‘costs’ to be minimized included a cost factor for the amount of rf power, and at times a cost for ‘jaggedness’.¹⁷ Relative weights for these costs were determined by trial and error. A conjugate-gradient minimization routine was used to minimize the cost function. Other optimal control methods were approached in similar

fashion.^{18,26,27} A relatively comprehensive review of these early approaches is available.²⁸

3.3 Shinnar–Le Roux (SLR) Pulse Design

The primary disadvantages of the optimal control theory approach were that the optimization was computationally intensive, and that it left some uncertainty as to whether or not a truly optimal design had been achieved. Thus, efforts continued to achieve more efficient algorithms for generation of amplitude modulated selective pulses. Noteworthy approaches include a unique approximation for linearizing the Bloch equations by Ngo and Morris,²⁹ and, more recently, approaches making use of inverse scattering theory.^{30–32} Still another approach was developed based on the use of digital filter design methods^{33–38} culminating in what has been termed the SLR algorithm.³⁹ Quite recently, Buonocore has demonstrated that the inverse scattering theory approaches and SLR algorithms are, roughly speaking, computationally equivalent.⁴⁰

In spite of their computational similarities, the SLR method appears to offer distinct advantages in that the digital filter design parameters can be interpreted in terms of rf pulse slice profile, so that the results of the design are known to a reasonable approximation even before the design is performed.³⁹ This prior knowledge facilitates the rf pulse design process. A brief overview of the SLR approach to rf pulse design is presented with the aid of Figure 3, which depicts a digital filter with equal ripple amplitudes in the passband and stopbands. The optimal filter, defined in terms of a polynomial in powers of inverse frequency, is one in which the ripple amplitudes are minimal given the length (order) of the polynomial and the width of the transition bands⁴¹ (Figure 3). The filter coefficients are associated with the rf amplitude steps.³⁹ The (iterative) solution for the polynomial coefficients is facilitated by prior knowledge of the number of ripple alternations, and approximation formulas exist predicting the ripple amplitudes given the other parameters of the filter.³⁹

Figure 3 Depiction of an equal-ripple digital filter, which is used as a basis for the SLR algorithm for generation of amplitude modulated frequency selective pulses. The amplitudes of the stopband ripples are not necessarily equal to those of the passband ripples

Figure 4 (a) An SLR-optimized 256-step 180° spin echo pulse. The symmetric pulse shape is required for a linear phase pulse, which is necessary for excitation or refocusing. (b) The resultant slice profile from the pulse in (a). The theoretical profile assumes that unit magnetization existed in the transverse plane prior to application of the pulse, and further assumes the presence of crusher gradients. (Reproduced with the computer program described in Matson¹⁹)

Finally, magnetization ripples in the slice profile can be estimated from the filter ripples, and the filter coefficients converted to a linear phase (necessary for refocusing) rf pulse through the SLR transform.³⁹ In addition, pulses producing nonlinear phase distributions (maximum or minimum phase³⁹) are also obtainable. Figure 4 illustrates a 180° rf pulse and resulting (theoretical) slice profile obtained by the SLR algorithm, while Figure 5 shows a maximum phase 180° inversion pulse along with its slice profile.¹⁹

3.4 Self-Refocused Pulses

In contrast to imaging and localized spectroscopy, where gradients are used to generate a range of frequencies across the object, excitation in high-resolution NMR spectroscopy is done in the absence of gradients. Thus, gradient refocusing is not possible, and self-refocused pulses are necessary for direct observation of the selectively excited spins. A surprising variety

of methods have been used for generation of self-refocusing or (prefocused) pulses.^{29,42–46} In some situations self-refocusing may be advantageous in imaging and localized spectroscopy as well, for instance in measurement of short T_2 species where the time for gradient refocusing would be detrimental.

4 FREQUENCY MODULATED PULSES

When rf inhomogeneity is small, optimized amplitude modulated pulses as discussed above can provide excellent selectivity with constant tip angle over the selected frequency range; however, these pulses are inherently sensitive to rf inhomogeneity. An advantage of the class of pulses based on the adiabatic sweep principle is that they are able to maintain both tip angle and selectivity over a range of rf power. This class of pulses is referred to as frequency modulated or adiabatic pulses. Unlike the amplitude modulated pulses, traditional adiabatic pulses operate on a spin locking mechanism, in which the spins follow the direction of the effective B_1 field. One of these selective pulses was the hyperbolic secant pulse, an inversion pulse whose form was obtained from the Bloch–Ricatti

Figure 5 (a) An SLR-optimized 256-step 180° maximum phase inversion pulse. A symmetric pulse shape (for linear phase) is not required, and the maximum (or minimum) phase pulse produces a superior profile (as compared with a linear phase pulse) for inversion or saturation. (b) The resultant slice profile from the pulse in (a). (Reproduced with the computer program described in Matson¹⁹)

Figure 6 (a) Radiofrequency amplitude (B_1) and frequency (Ω) sweeps for the hyperbolic secant inversion pulse. (b) Parametric plot of the locus of points touched by the tip of the effective field (scaled in units of frequency). (c) The angle between the z axis and the excitation vector at $\gamma q_z = 0$. The Figure shows the effective field for spins in the center of the inverted slice. For spins outside of the selected slice, the origin for the effective field would be offset in Ω such that the effective field would not change sign during the sweep. As discussed in the text, the spins follow the effective field; thus, only those spins experiencing a sign change in the effective field are inverted. (Reproduced by permission of Academic Press from Conolly et al.⁵³)

equation,^{14–16} and this pulse became widely used, particularly for surface coil experiments. As first noted^{47,48} and then aptly demonstrated with the image-selected in vivo spectroscopy (ISIS) experiment,⁴⁹ multiple acquisitions with different combinations of inversion pulses can be used to achieve localization.

The price paid for B_1 immunity was time and power. Following the introduction of the hyperbolic secant pulse, considerable work was done with frequency modulated pulses to shorten pulse lengths, reduce power requirements, improve immunity to B_1 inhomogeneity, or provide the capability for spin echo and additional tip angle pulses. Although the majority of this work was not aimed at developing good slice selection, there were a number of exceptions. Murdoch et al.¹⁷ showed that the slice profile of the hyperbolic secant pulse could be improved, albeit at the expense of reduction of B_1 immunity, and that somewhat analogous spin echo slice selective pulses could be defined. Ideas introduced initially by

Ugurbil et al.⁵⁰ were extended by Conolly et al.^{51–53} to generate slice-selective, adiabatic spin echo pulses. Figure 6 illustrates the action of a frequency modulated (adiabatic) inversion pulse.⁵³ A variety of adiabatic slice-selective excitation pulses have also been demonstrated, but all have drawbacks, including the need for two acquisitions to achieve the slice excitation,⁵⁴ perturbation of the out-of-slice magnetization,⁵⁵ or the requirement of complicated modulation of the gradients along with the rf waveform.⁵⁶

5 MISCELLANEOUS

5.1 Selective Pulses with Modulated Gradients

Practical considerations may limit the implementation of a desired selective rf pulse, namely: excessive power deposition

in the sample (SAR), maximum rf power available from the instrument or limits in the power handling capabilities of the probe, and available gradient strengths. As higher gradient strengths have become available the rf power considerations have become most important. To address these problems, as well as to make better utilization of the available gradient strength, Conolly et al.⁵⁷ proposed using variable rate selective excitation (VERSE) pulses where the gradient strength was varied during the selective pulse. In essence, the idea was to refabricate (or reformulate) the selective pulse by using increased gradients (and rf power) in regions where the original rf power was low, and reduced gradient strength (and rf power) where the original rf power was high. Since the SAR is proportional to the square of the integrated B_1 strength, reducing the peak power of a pulse yields reduced SAR.

In the VERSE technique the modified rf and gradient waveforms were determined by nonlinear constrained minimization methods which included constraints for gradient strength and slew rate limitations. Other implementations have since appeared.^{19,58} One limitation encountered with these pulses arises from chemically shifted resonances. As described below, the selected slice position differs for different chemically shifted species. With reformulated pulses, the applied gradient varies, resulting in smearing of the selected slice profile for chemically shifted resonances.^{19,57} The idea of reformulated pulses is demonstrated with Figure 7, which shows the gradient and rf waveforms for a reformulated version¹⁹ of the spin echo pulse of Figure 4.

5.2 Multidimensional Pulses

Multiple applications of selective excitation pulses in a single pulse sequence permit observation of signals from a small, well-defined volume. This approach has been used for localized spectroscopy studies, such as ISIS,⁴⁹ stimulated echo acquisition method (STEAM),⁵⁹ and point-resolved spectroscopy (PRESS).^{60,61} An alternative approach is to integrate gradient waveform modulation into the rf pulse design so that multidimensional spatial selectivity can be achieved in a single pulse. Unfortunately for spectroscopic applications this approach has limitations for excitation of multiple chemically shifted species, though other more suitable applications include excitation or suppression of flowing spins,⁶² and spectral-spatial excitation where simultaneous spatial and spectral selectivity is achieved in a single pulse.

One of the first approaches to multidimensional pulses was proposed by Bottomley and Hardy⁶³ to provide inversion of spins within a two-dimensional localized volume. This pulse applied a rotating gradient during the rf to invert a roughly cylindrical volume. Pauly et al.⁶⁴ have shown how an analysis of k -space trajectories can be used to design selective excitation pulses, and have applied these methods to large tip angle multidimensional pulses. The power of this approach is that the final two-dimensional pulse may be considered to be composed of concatenated, shallow tip angle pulses, so that linear FT analysis applies. This enables lengthy optimization procedures to be avoided. Suitable gradient waveforms have included spiral or pinwheel^{64–66} trajectories. Pulse shapes for excitation, inversion, and spin echo pulses have been optimized using approaches similar to those previously described, including simulated annealing methods,⁶⁷ and others.^{64,68}

Figure 7 Reformulated spin echo pulse from Figure 4(a). (a) Radiofrequency waveform of the reformulated pulse. The amplitude is increased and the time shortened compared with Figure 4(a); however, when executed with the gradient waveform of Figure 7(b), the slice profile is unchanged from Figure 4(b). (b) Gradient waveform for the reformulated pulse. The gradient dips at the center of the pulse to prevent the rf amplitude from exceeding a preset value (12 mT). The sharp dip at just over 1 ms is a resynchronization adjustment to maintain symmetry at the beginning and ends of the reformulated pulse.¹⁹ (Reproduced with the computer program described in Matson¹⁹)

The gradient waveforms necessary for multidimensional pulses can require significant power to be practical. By combining a two-dimensional selective pulse with an additional selectivity using blipped gradients, described as an echo planar (see *Echo-Planar Imaging*) pulse, Pauly et al.⁶² have demonstrated three-dimensional localization using conventional MRI gradient systems. The echo planar pulse consists of a sequence of subpulses, each selective about one axis, which are modulated by an envelope that is selective along another. To make this three-dimensional, each of the subpulses are made up of a two-dimensional spiral pulse. The ideas of two- and three-dimensional pulses are illustrated in Figures 8 and 9.

Spectral-spatial excitation is also possible;⁶⁹ this class of pulse provides selective excitation along one or two spatial axes while simultaneously exciting only those spins resonating over a specific frequency range. One application of these pulses is to provide fat suppression with slice-selective excitation of

Figure 8 Depiction of k -space trajectory of a three-dimensional selective pulse, along with the sidelobe structures produced by the pulse. (a) The series of eight disks in k_x - k_y , covered by three-turn constant-slew-rate spirals. (b) The sidelobe structure, showing the replicated main lobes along z and the radial sidelobe. The sidelobes are depicted closer than they actually occur. (Reproduced by permission from Pauly et al.⁶²)

the water signal, which is a requirement for echo planar imaging. Another application is to provide water suppression, which was used by Spielman et al.⁷⁰ for the refocusing pulse in a spectroscopic imaging experiment (see **Chemical Shift Imaging**). This same study also provides a practical demonstration of a two-dimensional pulse used to excite a large elliptical volume within the brain while excluding signal from the lipid regions near the edges of the head.

5.3 Chemical Shift Effects

An additional consideration for selective excitation occurs for chemically shifted resonances. In the presence of a constant applied gradient, slice-selective excitation produces a spatial shift for each chemically shifted resonance. If ω is the frequency separation between two resonances, then the shift between the slice selected for each resonance, Δ , will be given by $\Delta = G\omega/\gamma$, where G is the applied slice-selective field gradient. For example, for volume selective ^{31}P spectroscopy at a field strength of 1.5 T and with a field gradient of 5 mT m^{-1} , the relative localization error for the 23 ppm range between

monophosphate and β -ATP resonances is 6 mm in each gradient direction. Clearly this localization error can be reduced by using larger gradient strengths. These spatial errors become more significant for higher magnetic field studies, for observation of nuclei such as ^{13}C , which have wide chemical shift ranges, and for slice selection with narrow slice width.

When the gradient is nonconstant, as in reformulated and multidimensional pulses, the spatial shift is not constant during

Figure 9 Radiofrequency and gradient waveforms and resulting spin echo profiles for the pulse depicted in Figure 8. (a) Radiofrequency and gradient waveforms for the spin echo pulse. The blips in G_z provide the steps from one disk to another in Figure 8(a). (b) Simulated spin echo profile in the xy plane. The radial sidelobe is apparent in the simulation. (c) Simulated spin echo profile in the xz plane. The replicated main sidelobes are apparent in this orientation. (Reproduced by permission of Waverley from Pauly et al.⁶²)

the pulse, and degradation of the selection profile can occur.^{19,57,63,70} While an approach has been demonstrated for elimination of the spatial shift in slice-selective pulses,⁷¹ the length and complexity of this approach probably precludes its use in in vivo imaging and spectroscopy applications.

6 CONCLUSIONS

The field of RF pulse design has evolved to the point that a large number of computer-optimized pulses are available for a wide variety of MRI and MRS applications. Improved pulse design methods make use of the increased computational capabilities that have become available as well as new algorithmic methods. To summarize the current state of optimized pulse design for selective excitation:

1. Algorithms for amplitude modulated pulses have evolved to the point that it is feasible to perform the pulse design at run time with modern computer workstations, permitting the excitation profiles to be specifically tailored to the application. Unfortunately, the same is not yet true for tailoring frequency modulated pulses.
2. Little use has been made to date of reformulated or remapped pulses though the FOCI pulses,⁷² which were presented as improved pulses for the ISIS experiment, represent a class of remapped pulses. In addition, the increased flexibility, speed, and strength of the gradient systems being introduced and implemented on state-of-the-art MRI systems should accelerate the use of this class of pulses.
3. Multidimensional pulses, whose implementation and performance are also greatly facilitated by improved gradient systems, remain an unknown in terms of general use. A recent report demonstrates that they can be used to advantage in long TE PRESS localized spectroscopy to suppress lipid signals.⁷³ However, although they enable multidimensional selectivity within a single pulse, the pulses are long and lack the sharp profiles of the single-dimension selective pulses. Undoubtedly, their use will accelerate along with the improvements in gradient systems.
4. One area where current pulse designs are still lacking is a slice excitation pulse with immunity to B_1 inhomogeneity.
5. Other important areas for further investigation include faster algorithms for frequency modulated pulses which would allow for transition width to be traded off against immunity to B_1 inhomogeneity, and more efficient algorithms for generation of multidimensional pulses. The use of a small number of pulse parameters to be optimized may prove useful for speeding up optimization.⁶³

Selective Excitation Methods: Artifacts

Ian R. Young

The Robert Steiner MRI Unit, Hammersmith Hospital, London, UK

1 INTRODUCTION

This article describes some of the artifacts that arise in the process of selective excitation and from the use of gradient pulses to spoil (i.e. eliminate) transverse magnetization. It assumes that the pulse profiles intended by the user have been implemented correctly, and that the machine is performing well (so that if, for example, a certain rf pulse profile was designed to produce a 90° spin precession then, in fact, the right amount of rf field was delivered to the sample for the correct time). This section aims to suggest some of the ways in which errors can creep into apparently well-designed processes, the aim of which is to excite an accurate quantity of magnetization in the correct location.

Many of the problems described were most pernicious in the earlier stages of whole body MR, and can be avoided by some of the more sophisticated methods developed later (see *Selective Excitation in MRI and MR Spectroscopy*). However, problems with selection have contributed very substantially to the difficulties of measurement in whole body MR (see *Relaxation Measurements in Imaging Studies*) and, so, an understanding of the artifacts that can develop is an essential precursor to proper quantitation.

Clearly an evaluation of the detailed problems with any one form of data acquisition has to be left to its designer and users: a detailed survey of all problems is impracticable. This article can only point out potential sources of trouble.

2 APPEARANCE OF ARTIFACTS

It is important to note that what may be an artifact to one observer, may appear quite unimportant, or even be useful, to another. Thus, as long as the shape of its slice is not too distorted, a radiologist may still find an image quite usable: though be very suspicious of the presence of an unusual structure in it. A scientist might well not recognize the latter as existing or relevant, but might be very concerned about errors introduced by imperfections in the slice into his numerical values. Frequently, the only clue to the presence of such artifacts are seemingly anomalous numerical values. Subtle artifacts are the source of many concerns about measurement accuracy. An analogy can be drawn with spectroscopy where motion artifacts generally cause an apparent loss of signal-to-noise ratio, without producing an apparently erroneous spectral pattern that would immediately suggest the likely cause of the abnormality.¹

3 SLICE SELECTION ARTIFACTS

3.1 Impact of Flow and Motion

Flow effects (principally due to blood) are extremely common in any form of localized in vivo MR, and were exploited very early in the development of MRI.² Simplistically, if some fraction f of the blood in a slice is replaced in the sequence repetition time TR , the signal which results S is given by:

$$S = S_{0B} \exp\left(-\frac{TE}{T_{2B}}\right) \left\{ (1-f) \left[1 - \exp\left(-\frac{TR}{T_{1B}}\right) \right] + f \right\} \quad (1)$$

where S_0 is the total fully relaxed blood signal and the additional B subscripts refer to blood parameters. In practice, of course, the voxel may also include parenchymal signal leading to the fuller relationship:

$$S = xS_0 \exp\left(-\frac{TE}{T_{2B}}\right) \left\{ (1-f) \left[1 - \exp\left(-\frac{TR}{T_{1B}}\right) \right] + f \right\} + (1-x)S_0 \exp\left(-\frac{TE}{T_{2P}}\right) \left[1 - \exp\left(-\frac{TR}{T_{1P}}\right) \right] \quad (2)$$

where subscript P refers to the parenchyma, and x is the fractional contribution of blood the magnetization of which has reached a steady state saturation at the TR used to the fully recovered overall signal. Many of these parameters are difficult to determine even with good slice shapes, and are largely unresolvable with bad.

Very frequently (usually when cardiac gating is not used; not infrequently when it is) f is unstable, and characteristic ghosting artifacts develop. (See *Cardiac Gating Practice; Motion Artifacts: Mechanism and Control* and *Whole Body Magnetic Resonance Artifacts*.) These can be minimized in general with gating, and the use of sequences such as even echo rephasing,³ and motion artifact suppression technique⁴ (see *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control*), though complete elimination is rarely achieved.

Another motion artifact arises where the region being imaged moves through the slice (as in a transverse image of the liver). In this case, again, variable degrees of saturation develop even in nominally homogeneous regions of tissue as predicted by equation (2), though with variable fractions of unsaturated magnetization affecting both blood and parenchyma signals.

3.2 Time Constant Dependent Effects

Any degeneration in slice form tends to exacerbate the effects just described. Apart from machine maladjustment, the major slice selection artifacts arise from the impossibility of exciting all the spins in a region exactly to the degree required, while having no effect at all on those outside it. If a selected region is excited repetitively at a TR which is relatively short compared with T_1 there is likely to be enhanced signal from its edges. The original analyses were for the simple partial saturation (PS, or α - TR - α) sequence (where α is the flip angle).

Solving the Bloch equations in the presence of a gradient and rf pulse yields ultimately:⁵

$$M_{xyr} = \left\{ M_0 \left[1 - \exp\left(-\frac{TR}{T_1}\right) \right] \exp\left(-\frac{t_r}{T_2}\right) \sin \alpha_r \right\} \times \left\{ \left[1 - \exp\left(-\frac{TR}{T_1}\right) \cos \alpha_r \right] + \exp\left(-\frac{TR}{T_2}\right) \right\} \times \left[\exp\left(-\frac{TR}{T_1}\right) - \cos \alpha_r \right]^{-1} \quad (3)$$

where α_r is the precession angle of the rf pulse at a distance r from the reference plane; t_r is the time of the observation (post-rf pulse) and M_0 is the available, and M_{xy} the transverse, magnetization respectively. The value of α_r is derived from the Fourier transform of the pulse profile in conjunction with the applied gradient. Thus if the pulse profile is $P(t)$ for the duration (t_p) of the rf pulse, then

$$\int_{\omega=0}^{\infty} I_{\omega} d\omega = F \left\{ \int_{t=0}^{t_p} P(t) dt \right\} \quad (4)$$

where I_{ω} is the intensity of the rf at frequency ω . α_r is then defined by:

$$\alpha = \gamma I_{\omega_r} t_p \quad (5)$$

where $\omega_r = \gamma Gr$ relative to the reference.

Equation (3) can be simplified in general, except for short TR sequences (see *Whole Body Magnetic Resonance: Fast Low-Angle Acquisition Methods*), when $TR \gg T_2$, to give at the conventional echo at the center of data acquisition:

$$M_{xyr} = \frac{M_0 \left[1 - \exp\left(-\frac{TR}{T_1}\right) \right] \exp\left(-\frac{TE}{T_2}\right) \sin \alpha_r}{\left[1 - \exp\left(-\frac{TR}{T_1}\right) \cos \alpha_r \right]} \quad (6)$$

This relationship is that derived by Ernst and Anderson⁶ in their original description of Fourier transform MR, and yields the relationship:

$$\cos \alpha_M = \exp\left(-\frac{TR}{T_1}\right) \quad (7)$$

where α_M is the precession angle which results in the optimum signal-to-noise ratio per unit time for a sample with longitudinal relaxation time constant T_1 in an experiment with a sequence repetition time TR . Figure 1 illustrates the patterns that can develop, while Figure 2 is a practical demonstration of the predictions.

In Figure 1 a series of profiles are plotted for different ratios of TR/T_1 for the simple partial saturation experiment, using a slice the ideal form of which is given in Figure 1(a). The increasingly large fraction of the signal contribution from the slice edges as the ratio is reduced is apparent. Reducing α (the nominal precession angle) can improve slice shape. Notice that at $TR/T_1 = 0.1$, equation (8) predicts that $\alpha_M = 25.2^\circ$. Figure 2 shows how experiment confirms the theoretical predictions very exactly.

Figure 1 Predicted profile forms across a slice. (a) Desired slice form with $TR/T_1 \rightarrow \infty$ ($\alpha = 90^\circ$). (b) Predicted signal amplitude across the slice in Figure 1(a) for $TR/T_1 = 2$; $TR/T_1 = 0.5$; and $TR/T_1 = 0.1$ (all with nominal $\alpha = 90^\circ$). (c) Predicted amplitudes for $TR/T_1 = 0.1$, but with nominal values of $\alpha = 60^\circ$ and 15° respectively. T_2 , TE assumed constant in all experiments; M_0 taken as unity

Similar problems exist with other sequences to some extent, as long as all the rf pulses in them are selective (each defining a similar width of slice, such as might be needed for a multi-slice acquisition with contiguous, or closely adjacent, slices).

Figure 2 Pair of images showing the actual form of slices. (a) $TR/T_1 = 5$ ($\alpha = 90^\circ$); (b) $TR/T_1 = 0.2$ ($\alpha = 90^\circ$). The images were taken by using a conventional slice-selection gradient pulse with a sinc rf pulse, truncated at the third duration on either side of zero. Rf pulse duration was 4 ms; nominal slice width 8 mm. The normal duration of the rephasing pulse was extended, and then the gradient reversed, to form an echo, during which data was sampled. The process was repeated 64 times to improve the signal-to-noise ratio, and the results collected, zero filled to 256 points, Fourier transformed, and displayed. (Reproduced with permission of Academic Press from Young, Bryant, and Payne, *Magn. Reson. Med.*, 1985, 2, 361)

Sequence variants in which nonselective inverting pulses are used tend to minimize the problem.

From a practical point of view, it is apparent that in the body, where T_1 values for different tissues vary by the best part of an order of magnitude, slice shape can change quite markedly from place to place in it. Partial volume effects, meaning that issues with significantly different T_1 values occupy opposite sides of the slice in the same location in the plane, can result in the slice profile being quite different from one side to the other.

3.3 Consequence for Measurement

It is also clear from the foregoing how the accuracy of measured values can be destroyed. Generally speaking, techniques in which partial saturation sequences are used result in an underestimate of the T_1 of slowly relaxing tissues. However, because they are relatively fast, a number of attempts have been made to exploit them, particularly in the early 1980s.⁷ Examination of the problems found with their use are instructive in showing how hard it can be to destroy unwanted magnetization by gradient spoiling pulses.⁸

The principle of gradient spoiling assumes that the net signal from a region is given by:

$$S = \int_{r=-\infty}^{+\infty} S_r \sin \gamma G r t_p dr = 0 \quad (8)$$

where t_p is the duration of the pulse application, G the gradient, and S_r the available signal in a strip of width δr at distance r from the center of the slice. Clearly, if S_r is nearly constant, $S \rightarrow 0$ more quickly than if S_r is significantly nonuniform (particularly if it has large symmetrical peaks in it).

Similarly apparently efficient saturation techniques such as the use of a group of rf pulses, even nonselective ones, interleaved with gradient pulses can result in complex modulation patterns which, ultimately, make proper destruction of the magnetization (the actual aim of saturation) very difficult to achieve. This is illustrated in Figure 3 which shows the magne-

Figure 3 Magnetization excited by a nominally 10 mm-wide slice in a phantom of T_1 of 1600 ms, 200 ms after the start of a burst saturation sequence (three rf pulses each 1 ms long, each followed immediately by a gradient pulse with 1 ms rising and falling edges, and 5 ms period at 15 mT m⁻¹ amplitude). (Reproduced with permission of Academic Press from Young, Bydder, and Bryant, *Magn. Reson. Med.*, 1985, 11, 129)

tization excited by a selective 90° excitation, 200 ms after the commencement of a burst of three nonselective rf pulses with interleaved spoiling gradients. The magnetization pattern can be predicted theoretically through the process but the evaluation of coherence pathways is only really instructive as a didactic exercise.

3.4 Chemical Shift Effects

These are discussed more fully elsewhere (see *Selective Excitation in MRI and MR Spectroscopy*) and are described here only for completeness.

If there are two moieties with a chemical shift of δ between them in a region where a slice is selected using a gradient of strength G , then the effective centers of the two slices formed, one for each component, are offset by a distance d given by

$$d = \frac{\delta}{\gamma G} \quad (9)$$

The effects of this artifact are much more pronounced with nuclei other than hydrogen such as ^{13}C , where the spectral dispersion is much greater, or phosphorus (see *Whole Body Studies: Impact of MRS*), particularly in methods where multiple selective excitations are used such as Image-Selected In Vivo Spectroscopy.⁹ At 1.5 T, the magnitude of the offset for a chemical shift of 10 ppm in a selective gradient of 5 mT m⁻¹ is around 0.3 mm, and the problem can be substantially discounted in most proton work.

4 EFFECTS OF MULTISLICE AND MULTIECHO ACQUISITIONS

Because of the relative efficiency with which these methods use available time, their application is very widespread. However, as has emerged lately, details of the way in which they are implemented can introduce changes in the magnetization that have significant impact on the accuracy of data acquired using them. The notes which follow are designed only to give guidance as to where there may be problems, and readers should consult related articles for further explanation and understanding.

4.1 Artifacts in Multislice Acquisitions

4.1.1 Direct Contamination of One Slice by Another

If the slice shape is poor, with significant excitation of side-lobes, it is likely that some fraction of the spins in a slice will have been excited at a time other than (and less than) the intended TR . Depending on the order in which slices are interrogated this results in both a reduction in available signal, and a distortion of expected partial volume effects, as the near neighbors on one side of a slice will inevitably be excited at different times from those on the other.

4.1.2 Off-Resonance Irradiation Effects

As was pointed out by Dixon et al.,¹⁰ the on-resonance excitation of one slice is an off-resonance perturbation of its

neighbors. This results in a degree of saturation of the broad spectral line of the cell wall proteins, and some attenuation, potentially, and change of effective time constants, of the narrow water line (which is what is observed) (see *Magnetization Transfer between Water and Macromolecules in Proton MRI* and *Magnetization Transfer and Cross Relaxation in Tissue*). The model used here is discussed fully in those articles.

The behavior of a two-pool system was modeled by Förse and Hoffman,¹¹ to give the relationship:

$$S_A = \left[S_{0\text{ASAT}} + (S_{0A} - S_{0\text{ASAT}}) \exp\left(-\frac{t}{T_{1\text{ASAT}}}\right) \right] \times \exp\left(-\frac{TE}{T_2}\right) \quad (10)$$

where subscript A refers to signals from the visible pool, and the observation is made just after a period t of off-resonance irradiation. S_{0A} is the available signal after an extended recovery period; $S_{0\text{ASAT}}$ that available after prolonged irradiation, and $T_{1\text{ASAT}}$ the effective time constant of the evolution of the saturated situation.

If the slice to be observed is the x th in the series, its signal is then given by assuming the rf pulse durations are short compared with T_1 of the visible pool:

$$S_{\text{xobs}} = \left[S_0 - \exp\left(-\frac{TR_x}{T_{1(x-1)}}\right) (S_0 - S_{(x-1)}) \right] \times \exp\left(-\frac{TE}{T_2}\right) \quad (11)$$

where $S_{(x-1)}$ is the magnetization available after the previous excitation. $T_{1(x-1)}$ is the effective relaxation time of the magnetization in the state it had reached after the recovery of the $(x-1)$ th slice, determined by the order and timing of acquisition of previous nearby slices. TR_x is the time since the last slice was acquired. S_0 is the fully recovered magnetization of the slice. In practice there are no long recovery periods and some sort of steady state develops which is dependent on the pulse pattern in use. As has been observed from the first in vivo experiment,¹² magnetization transfer effects in tissue are substantial, so that artifacts from this source are a real problem.

4.2 Artifacts of Multiecho Acquisitions

4.2.1 Stimulated Echo Effects

Any multiple pulse train such as that used in a multiecho data acquisition can result in the generation of multiple complex echoes, which can develop to produce interference-like patterns on the resultant images. Stimulated echoes¹³ are only one significant aspect of effects produced by more or less adequate rf pulses in the presence of complicated gradient patterns.

4.2.2 Magnetization Transfer Artifacts

As was pointed out by Constable et al.,¹⁴ magnetization transfer effects also contaminate sequences in which many rf refocused echoes are used [such as, for example, 'rapid acquisition with relaxation enhancement' (RARE¹⁵) and its variants (see *Multi Echo Acquisition Techniques Using Inverting Radiofrequency Pulses in MRI*)]. Because the relative time-

constant weighting in such sequences is readily modified by the phase encoding order selected from one data acquisition to another, the relative extent of saturation at the time of formation of the echoes at the center of k -space is also variable if it is appreciated that a succession of rapid spin-inverting pulses has a quasisaturating effect on the system. The arguments involved are similar to those deployed in Section 4.1.2 above, and, in any event, are much more extensively described in Constable et al.¹⁴

4.2.3 Unintentional Diffusion Weighting

Another problem to which multiple acquisition sequences can easily become exposed is an over exuberant use of gradients for spoiling out-of-slice and other unwanted magnetization. Modern machines can have very powerful gradients, and putting a couple of large spoiling pulses on either side of a slice-selective 180° pulse seems to require little time (which can generally be used profitably for other, phase encoding, purposes, for example) and is a useful precaution.

Following the Stejskal and Tanner pulsed gradient spin echo experiment,¹⁶ and assuming no significant contribution from the central gradient pulse (present during the rf inversion pulse) the resulting signal S_n (after the n th inverting pulse) of an acquisition with a very long TR preceding it is given by:

$$S_n = S_0 \exp \left[-\frac{TE_n}{T_2} - nD\gamma^2 G^2 \delta^2 (\Delta - \delta/3) \right] \quad (12)$$

where the spoilers round each rf pulse are assumed identical, of amplitude G , duration (effective) δ , and with a leading edge separation of Δ .

If $G = 20 \text{ mT m}^{-1}$; $\delta = 3 \text{ ms}$; $\Delta = 6 \text{ ms}$; $D = 3 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$, and $n = 16$, then the signal (S_{16}) is about 6% smaller than it would be in the absence of the spoiling pulses. While this effect is small, an increase to 25 mT m^{-1} increases the effect to 9.2%, and it is clear that care must be taken in designing sequences for quantitative studies.

Large spoilers in any in vivo studies (including spectroscopy) must be applied with care, particularly when studies of tissues with marked known anisotropies (as in the brain^{17,18} and muscle¹⁹) are being undertaken.

5 CONCLUSION

The foregoing can only be an illustration of the artifacts arising from sequence design and implementation in vivo. Tissue is a very complex system and many artifacts are a function of the tissue parameters present in the region being studied. Thus, for example, a slice which straddles a region containing normal and abnormal tissue can have significantly different profile shape at either side of the same planar location.⁵ It is only by considering all the likely contaminating circumstances built into the data acquisition that useful quantitative MRI (or localized MRS) can be expected. In the majority of cases clinical imperatives (the need for multiple data acquisitions while at the same time maintaining high patient throughput) militate against the prolonged recovery times and single slice procedures optimal for measurement accuracy.

Spatial Encoding Using Multiple rf Coils: SMASH Imaging and Parallel MRI

Daniel K. Sodickson

Beth Israel Deaconess Medical Center and Harvard Medical School,
Boston, MA, USA

1 INTRODUCTION

The speed of MR image acquisition has increased dramatically since the 1980s through a combination of technological and methodological advances. Nevertheless, many clinical applications of MRI continue to require motion compensation in some form. In body regions containing moving structures such as the heart or diaphragm, serious artifacts can arise if scan times exceed the characteristic time scales of physiologic motion. Accurate tracking of dynamic processes, such as cardiac contraction or the arrival and uptake of intravenous contrast agents, may require high temporal resolutions without undue sacrifices in spatial resolution. Meanwhile, the fastest imaging sequences and the most state-of-the-art scanners are approaching certain basic limits of imaging speed. These limits, which have both a technological and a physiological component, are related to the maximum switching rates of magnetic field gradients and rf pulses. Most of the fast imaging sequences now in use – echo planar imaging (EPI), fast low angle shot (FLASH), turbo spin echo (TSE), spiral, or BURST, for example – achieve their high speeds by optimizing the strengths, the switching rates, and the patterns of applied gradients and pulses. Beyond a certain threshold, however, rapidly switched field gradients are known to produce neuromuscular stimulation, while excessively dense rf pulse trains can lead to unacceptable levels of rf energy deposition and heating of tissue. One common feature of fast imaging sequences is that they all acquire data in a sequential fashion. Regardless of the particular sequence the acquisition follows, the MR signal is always acquired one point and one line at a time, with each separate line of data requiring a separate application of field gradients and/or rf pulses. Therefore, imaging speed is generally limited by the maximum switching rates compatible with scanner technology and patient safety.

Recently, a new paradigm of parallel MRI has been used to increase imaging speeds beyond the basic limits just described. The term ‘parallel MRI’ may be used to describe any MRI strategy in which multiple MR signal data points are acquired *simultaneously*, rather than one after the other. Parallel imaging strategies in general require the use of multiple distinct detectors, with each detector providing some component of distinct spatial information to the image. (A many-detector CCD camera is a familiar optical example of a parallel imaging device while a FAX machine is an example of a sequential line-scanning device.) For MRI in particular, some of the burden of spatial encoding traditionally accomplished by field gradients

may be shifted instead to arrays of rf coils. Recent work has shown that coil arrays may be used, in combination with appropriate image reconstruction strategies, to encode and detect multiple MR signal or image components simultaneously and thereby to multiply the speed of existing imaging sequences *without* increasing gradient switching rate or rf power deposition.

2 THE HISTORY OF PARALLEL MRI

Radiofrequency coil arrays were first developed for use in MRI in the late 1980s. Prior to that time, single volume or surface coils were typically used for signal detection, or else pairs of coils were arranged in quadrature to increase signal-to-noise ratio (SNR). Work by Roemer and co-workers demonstrated that arrays of suitably decoupled surface coils could be used to achieve further substantial SNR increases^{1,2} (see *Whole Body Machines: NMR Phased Array Coil Systems*). When used in combination with traditional gradient-encoding sequences, coil arrays increased the achievable SNR for any given field of view (FOV) in any given imaging time, but ultimate imaging speed was still governed by the imaging sequence and the gradient hardware.

The fact that spatial information from coil arrays might also be used directly for the encoding and decoding of images was realized in principle relatively early in the development of MR-compatible arrays. The simplest manifestation of the parallel imaging principle was the use of spatially separated coils to image distant and nonoverlapping body regions simultaneously. More challenging was the prospect of imaging a continuous FOV rapidly using detectors overlapping in space and/or sensitivity. An early theoretical proposal by Carlson suggested that the Fourier coefficients of signal voltages in multiple coils disposed around a cylinder could be used to calculate multiple k -space lines for magnetization within that cylinder.³ Hutchinson and Raff suggested in 1988 that a large array of narrow loops surrounding an object could, in principle, be used to acquire an image without the use of any phase-encoding gradients at all.⁴ Other proposals followed, and these proposals fall into two general categories: massively parallel and partially parallel strategies.

In massively parallel strategies, the number of detectors approaches the number of data points or lines. These techniques aim to replace gradient encoding entirely, with resulting dramatic improvements in imaging speed. The original massively parallel proposal of Hutchinson and Raff was intended to show theoretical feasibility, and no direct practical implementation was suggested.⁴ A subsequent proposal for massively parallel imaging was made by Kwiat, Einav, and Navon in 1991.⁵ Their study included a more detailed investigation of practical issues, though no images were presented. A preliminary array design based on the general principles of this proposal was presented in 1995.⁶

In partially parallel imaging strategies, the number of detectors is significantly smaller than the number of data points. Spatial encoding using multiple rf coils is used to supplement the spatial encoding normally accomplished using magnetic field gradients. Kelton, Magin, and Wright,⁷ and later Ra and Rim^{8,9} described a ‘subencoding’ approach by which aliased

Table 1 Parallel MRI techniques

Technique	Sensitivity calibration	Image reconstruction
Partially parallel		
<i>k</i> -space techniques		
Carlson and Minemura (1993) ¹⁰	Known volume coil sensitivities	<i>k</i> -space series expansion
SMASH ^a (1996) ¹¹	Surface coil sensitivity reference (phantom, in vivo, AUTO-SMASH)	<i>k</i> -space linear combination (spatial harmonics)
Image domain techniques

Ra and Rim (1991, 1993) ^{8,9}	Pixel-by-pixel image reference	Pixel-by-pixel matrix inversion (subencoding)
SENSE ^a (1997) ¹²	Pixel-by-pixel sensitivity extraction from full reference images	Pixel-by-pixel matrix inversion (subencoding)
Massively parallel		
Hutchinson and Raff (1988) ⁴	Not discussed	Inverse source
Kwiat, Einav, and Navon (1991) ⁵	Point source references	Inverse source

SMASH, simultaneous acquisition of spatial harmonics; SENSE, sensitivity encoding technique.

^aIn vivo results have been published for this technique.

component coil images acquired rapidly with reduced phase encoding may be ‘unaliaised’ using information about component coil sensitivities. Carlson and Minemura proposed using nested volume coils with differing sensitivity patterns to approximate multiple *k*-space lines from a series expansion.¹⁰ In 1997, SiMultaneous Acquisition of Spatial Harmonics (SMASH)¹¹ was introduced, and the first accelerated in vivo MR images using a parallel imaging strategy were obtained. The SMASH technique uses linear combinations of component coil signals from a surface coil array to replace time-consuming gradient steps directly. Following the introduction of SMASH, the subencoding principle was revisited and refined in the SENSitivity Encoding technique (SENSE) of Prüssmann, Weiger, and co-workers,¹² which has also been used recently to obtain accelerated in vivo images. At the present time, various other research groups both in academia and in industry have also begun to investigate parallel imaging strategies.

Table 1 lists the various proposed parallel MRI techniques, further categorized by coil sensitivity calibration and image reconstruction method. The principal message of this table is that there are numerous ways to extract spatial information from an array of rf detectors. We will now discuss some of these methods in greater detail, emphasizing approaches for which in vivo results have already been published, and which are likely to be well suited for clinical MRI. We will begin with the SMASH technique,¹¹ for which the broadest range of in vivo results have been achieved to date. We will then discuss the image-domain subencoding reconstruction techniques.

3 SMASH IMAGING

3.1 Theory

The SMASH technique exploits sensitivity variations in a surface coil array to substitute for spatial modulations normally produced by phase-encoding gradients.¹¹ This use of coil encoding in place of gradient encoding allows the whole of *k*-space to be traversed using a reduced number of phase-encoding gradient steps, thereby reducing image acquisition times.

The function of phase-encoding gradients is to impose sinusoidal modulations of magnetization across the image plane. The MR signal integrated against these sinusoids then corresponds to spatial Fourier components of the image, or the familiar *k*-space lines. Figure 1 illustrates schematically this well-known effect. In the figure, sinusoidal modulations of varying spatial frequency, resulting from spin evolution in phase-encoding gradients of varying strength, are shown next to their associated *k*-space lines. In the SMASH technique, some of these sinusoidal modulations, or ‘spatial harmonics’, are generated by manipulations of component coil sensitivities, rather than by gradient-induced modulations of magnetization.

An array of rf coils contains spatial information in the form of its component coil sensitivities (Figure 2). In a linear surface coil array with adjacent components, each coil *j* has a distinct but overlapping sensitivity $C_j(x, y)$. By forming appropriate linear combinations of component coil signals (Figure 3), we may generate composite sensitivity profiles C^{tot} which oscillate in

Figure 1 A *k*-space schematic, indicating the spatial modulations resulting from phase-encoding gradients. Gradient steps on either side of the central $k=0$ line correspond to various harmonics of spin modulation across the image plane

Figure 2 The rf sensitivities of a linear coil array. Each of the three overlapping sensitivity distributions corresponds to one of the three component coils in the array pictured at the top. (The conductor paths of adjacent component coils are also typically overlapped, as shown in this example, to minimize inductive coupling between coils.) Only sensitivity magnitudes are shown here. In practice, coil sensitivities may also have spatially varying phase distributions

much the same way as the gradient-induced modulations of Figure 1:

$$C^{\text{tot}}(x, y) = \sum_j n_j C_j(x, y) \approx \exp(im\Delta k_y y) \quad (1)$$

where n_j are complex weight factors, m is an integer, and $k_y = 2\pi/\text{FOV}$ is the minimum k -space interval corresponding to the desired FOV.

If a composite sensitivity profile generated in this way forms an accurate spatial harmonic pattern, the same k -space step is produced as would have resulted from a traditional gradient step.¹¹ In other words, each combined signal S^{tot} , generated from linear combinations of component coil signals S_j using the weights n_j from Equation (1), is shifted in k -space by an amount $(-m\Delta k_y)$:

$$\begin{aligned} S_j(k_x, k_y) &= \iint dx dy C_j(x, y) \rho(x, y) \exp\{-ik_x x - ik_y y\} \\ S^{\text{tot}}(k_x, k_y) &= \sum_j n_j S_j(k_x, k_y) \\ &= \iint dx dy \sum_j n_j C_j(x, y) \rho(x, y) \exp\{-ik_x x - ik_y y\} \\ &= \iint dx dy C^{\text{tot}}(x, y) \rho(x, y) \exp\{-ik_x x - ik_y y\} \\ &\approx \iint dx dy \rho(x, y) \exp\{-ik_x x - i(k_y - m\Delta k_y)y\} \\ &\approx \tilde{\rho}(k_x, k_y - m\Delta k_y) \end{aligned} \quad (2)$$

Figure 3 Multiple spatial harmonic profiles derived by linear combination of component coil sensitivities in an eight-element array

where $\rho(x, y)$ represents the spatial distribution of spin density in the image plane and $\tilde{\rho}$ is its spatial Fourier transform. This k -space shift is precisely the same shift as would be produced by evolution of spins with gyromagnetic ratio γ for time t_y in a y gradient of magnitude G_y , with $\gamma G_y t_y = -m\Delta k_y$.

Such a coil-encoded k -space step combines naturally with any gradient-encoded k -space steps. When a coil array with multiple elements is used, multiple harmonics may be generated from a single data set (Figure 3). The result is that a reduced number of phase-encoded lines (thick lines in Figure 4) may be acquired in a reduced acquisition time, and the remaining lines of k -space (thin lines in Figure 4) may be reconstructed using linear combinations of component coil signals. If a total of M spatial harmonics are generated, then M lines of k -space may be reconstructed for each application of a phase-encoding gradient. The full signal matrix may, therefore, be generated in a fraction $1/M$ of the usual acquisition time.

3.2 Implementation

An important first step in a practical SMASH implementation is to measure the rf sensitivities of the various array elements. These sensitivities may be extracted in a straightforward manner from images of homogeneous phantoms, since any intensity variations in such images may be traced to variations in coil sensitivity. Typically, intensity profiles across an image plane of interest are extracted from a stored phantom data set and are used as sensitivity references. (Often, intensity profiles along a single central line of the image plane suffice for calibration.) For cases in which phantom sensitivity reference measurements are cumbersome or inaccurate (for example when flexible coil arrays are used, the particular conformations of which for any given patient are not known a priori), sensitivity profiles may also be obtained in vivo by examining component coil images in regions of comparatively uniform spin density such as the spine. Alternative in vivo sensitivity calibration procedures, such as the self-calibrating approach

Figure 4 Schematic k -space trajectory for a partially parallel acquisition using five spatial harmonics. Thick lines represent k -space lines corresponding to applied phase-encoding gradient steps, while thin lines represent additional k -space lines reconstructed using the linear combinations shown in Figure 3. The additional reconstructed lines substitute for omitted phase-encoding gradient steps

called AUTO-SMASH,¹³ may be used for imaging in regions of heterogeneous spin density such as the thorax, where large differences in signal between the heart and lungs preclude straightforward estimation of rf sensitivity. In AUTO-SMASH, a small number of reference k -space lines are added to the acquisition, and the relation between these reference lines and the usual MR signal data lines are used to ‘train’ SMASH reconstructions directly in k -space.

Following sensitivity calibration, the sensitivity profiles are fitted to the desired spatial harmonic functions, using a numerical optimization algorithm with the complex weight factors n_i as fitting parameters. For favorable array geometries, the resulting fits can, in practice, be quite as good as the schematic fits shown in Figure 3.

The remaining steps in the SMASH reconstruction procedure are summarized in Figure 5. The left-hand side of Figure 5 shows a k -space schematic, and the right-hand side shows image data from a water phantom at each of the corresponding stages of reconstruction. With the necessary weights in hand, MR signal data are acquired simultaneously in the coils of the array. A fraction $1/M$ of the usual number of phase-encoding steps are applied, with M times the usual spacing in k -space (Figure 5A, left). The component coil signals acquired in this way correspond to images with a fraction $1/M$ of the desired FOV (Figure 5A, right). With $1/M$ times fewer phase-encoding steps, only a fraction $1/M$ of the time usually required for this FOV is spent on data collection.

Next, the appropriate M linear combinations of the component coil signals are formed to produce M shifted composite signal data sets (Figure 5B). The composite signals are then interleaved to yield the full k -space matrix (Figure 5C, left), which is Fourier transformed to give the reconstructed image (Figure 5C, right).

The schematic summary in Figure 5 shows a SMASH reconstruction with acceleration factor $M=2$ using a 3-element rf coil array. Substantially larger factors are possible, however, when coil arrays with larger numbers of elements are used. In fact, for favorable image plane and coil array geometries, the maximum achievable SMASH acceleration factor M is equal to the number of independent component coils in the array, since a maximum of M distinct harmonics may be generated using a total of M independent coils. Since generation of spatial harmonics does not depend upon how the gradient-encoded k -space lines were generated, the SMASH reconstruction is to a large extent sequence independent. Nearly all existing rapid imaging sequences may be accelerated in this manner, and, to date, SMASH has been successfully tested with a wide range of sequence types. Both two-dimensional and three-dimensional acquisitions are amenable to acceleration using SMASH, provided distinct coil sensitivity information is available along one or more phase-encoding directions.

3.3 In Vivo Results

The improvements in imaging efficiency afforded by a parallel imaging strategy may be put to use in a number of ways. The following examples demonstrate some of the applications for which SMASH imaging has been used to increase imaging speed and improve image quality.

Reductions in breath-hold duration for scans requiring breath-holding can be achieved, which increases patient comfort and compliance and allows scans free of respiratory motion artifact in patients incapable of prolonged breath-holds. Figure 6 demonstrates a twofold reduction in breath-hold duration for abdominal MR imaging.

Improvements in spatial resolution can be achieved in any given imaging time: images of increased spatial resolution may

Figure 5 Schematic representation of the SMASH reconstruction procedure (left: k -space cartoon, right: corresponding phantom images). (A) Acquisition of data with reduced phase encoding. (B) Formation of shifted data sets using spatial harmonic combinations. (C) Interleaving of shifted data sets to generate a full signal matrix, corresponding to an image with full FOV

be generated in a given acquisition time by carrying the faster SMASH acquisition farther out in k -space. Figure 7 shows the use of SMASH for spatial resolution enhancement in a cardiac scan. Additional resolution benefits can result from the use of SMASH or other partially parallel techniques in single-shot imaging sequences such as HASTE (half-Fourier single-shot turbo spin echo), EPI, or BURST.¹⁴ Indeed, single-shot images with both reduced acquisition time *and* increased spatial resolution have been obtained. This is possible because a reduced acquisition time also entails reduced relaxation, and hence reduced attenuation of high spatial frequencies in single-shot sequences.¹⁴

Improvements in temporal resolution (i.e., reductions in image-acquisition interval for gated or ungated scans) minimize undesired effects of physiologic motion while allowing accurate tracking of time-dependent phenomena. Figure 8 illustrates a twofold and a fourfold reduction in acquisition window at fixed spatial resolution in cardiac MR images. These progressive increases in temporal resolution result in progressively reduced motion blurring of the right coronary artery and other cardiac structures in the SMASH images. SMASH has also been used to increase true frame rate in real-time cardiac MR scans up to and beyond current two-dimensional echocardiographic frame rates.

Reductions in the overall duration of long MR scans increase patient comfort and compliance and also increase the throughput of clinical MR scanners and the cost-effectiveness of MR diagnosis. Noncontrast MR coronary angiograms obtained using SMASH are shown in Figure 9. Reduction in overall acquisition time in these navigator-gated scans has the further advantage of reducing long-term diaphragmatic drift over the course of the scans.

4 IMAGE-DOMAIN SUBENCODING TECHNIQUES

4.1 Theory

A subencoding image reconstruction begins at the same starting point as a SMASH reconstruction – namely, with a set of component coil signals acquired using a reduced number of phase-encoding gradient steps. Fourier transformation of these signal sets results in aliased component coil images like those shown in Figure 5A. From that point on, the subencoding reconstruction operates entirely in the image domain.

The basis of the technique lies in the fact that each pixel in an aliased image is in fact a superposition of multiple pixels

Figure 6 Turbo spin echo (TSE) images taken along the thoracic and lumbar spine of a healthy adult volunteer, demonstrating the use of SMASH imaging for reduction of breath-hold times in vivo (TR 700 ms, TE 32 ms, 9 echoes per excitation, in-plane spatial resolution $1.9 \text{ mm} \times 1.0 \text{ mm}$). These images were obtained using four active elements of a six-element circularly polarized spine array on a 1.5 T Siemens Vision imaging system. The reference image was obtained in a breath-hold lasting 22 s and reconstructed using a standard sum of squares combination of component coil images.¹ The SMASH image with the same final spatial resolution and FOV was obtained in only 11 s

from a corresponding full unaliased image (Figure 10). In other words, as a result of Nyquist aliasing, an M -times aliased image I^{fold} is related to the full image I^{full} as follows:

$$I^{\text{fold}}(x, y) = I^{\text{full}}(x, y) + I^{\text{full}}(x, y + \Delta y) + I^{\text{full}}(x, y + 2\Delta y) + \dots + \sum_{m=0}^{M-1} I^{\text{full}}(x, y + m\Delta y) \quad (3)$$

When I^{fold} is acquired using a single coil, this superposition cannot be ‘unfolded’ without a priori knowledge of the full image.

The situation changes when an array of coils is used. The full image I_j^{full} in each coil j is actually made up of two pieces: the spin density ρ , and the coil sensitivity function C_j :

$$I_j^{\text{full}}(x, y) = C_j(x, y)\rho(x, y) \quad (4)$$

and in an array, each component coil j has a different sensitivity C_j . Therefore, we now have multiple ‘views’ of the aliasing that can be used to deduce just how much of each

aliased pixel belongs at any position in the full image. Substituting Equation (4) into Equation (3) gives

$$I_j^{\text{fold}}(x, y) = \sum_{m=0}^{M-1} I_j^{\text{full}}(x, y + m\Delta y) = \sum_{m=0}^{M-1} C_j(x, y + m\Delta y)\rho(x, y + m\Delta y) \quad (5)$$

For any particular aliased pixel (x, y) , this may be written as follows:

$$I_j^{\text{fold}} = \sum_{m=0}^{M-1} I_{jm}^{\text{full}} = \sum_{m=0}^{M-1} C_{jm}\rho_m \quad (6)$$

where $I_{jm}^{\text{full}} \equiv I_j^{\text{full}}(x, y + m\Delta y)$, $C_{jm} \equiv C_j(x, y + m\Delta y)$, and $\rho_m \equiv \rho(x, y + m\Delta y)$.

Let us study the particular example (illustrated in Figure 11) in which a four-coil array is used with a factor of three aliasing. We may write

Figure 7 Coronal cardiac images showing the use of SMASH for increased spatial resolution (2D segmented- k -space FLASH, 9 echoes per segment, TR 14.4 ms, TE 7.3 ms, custom-designed four-element array, Siemens Vision scanner). The reference image has a matrix size of 144×256 , corresponding to an in-plane resolution of $2.2 \text{ mm} \times 1.2 \text{ mm}$. The SMASH image has double the spatial resolution in both dimensions (288×512 matrix size, in-plane resolution $1.1 \text{ mm} \times 0.6 \text{ mm}$). Both images were obtained in a breath-hold lasting 16 cardiac cycles. A long segment of the right coronary artery (thick black arrows) may be seen in both images but is notably sharper in the higher-resolution SMASH image. Branches of the left coronary system (thick white arrow) may also be discerned in the SMASH image, whereas they are not seen in the reference image. Finally, internal mammary arteries (thin white arrow), invisible in the reference image, may just be discerned running down the center of the SMASH image

$$\begin{aligned}
 I_1^{\text{fold}} &= C_{11}\rho_1 + C_{12}\rho_2 + C_{13}\rho_3 \\
 I_2^{\text{fold}} &= C_{21}\rho_1 + C_{22}\rho_2 + C_{23}\rho_3 \\
 I_3^{\text{fold}} &= C_{31}\rho_1 + C_{32}\rho_2 + C_{33}\rho_3 \\
 I_4^{\text{fold}} &= C_{41}\rho_1 + C_{42}\rho_2 + C_{43}\rho_3
 \end{aligned} \tag{7}$$

This equation may be rewritten in matrix form as

$$\begin{bmatrix} I_1^{\text{fold}} \\ I_2^{\text{fold}} \\ I_3^{\text{fold}} \\ I_4^{\text{fold}} \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ C_{21} & C_{22} & C_{23} \\ C_{31} & C_{32} & C_{33} \\ C_{41} & C_{42} & C_{43} \end{bmatrix} \cdot \begin{bmatrix} \rho_1 \\ \rho_2 \\ \rho_3 \end{bmatrix} \tag{8}$$

or, in other words,

$$\mathbf{I}^{\text{fold}} = \mathbf{C}\rho \tag{9}$$

As long as the number of coils N_c is greater than or equal to the aliasing factor M (as in our exemplary case for which $N_c = 4$, $M = 3$), Equation (9) may be inverted:

$$\rho = \mathbf{C}^{-1}\mathbf{I}^{\text{fold}} \tag{10}$$

and the unaliased spin density over the full FOV may be determined. This ‘unaliasing’ approach bears some kinship with the principle of computed tomography, in the sense that multiple different ‘views’ or projections are used to extract full two-dimensional image information.

4.2 Implementation

Subencoding implementations differ from SMASH implementations primarily in their approaches to sensitivity calibration and in the nature and numerical stability of their image reconstruction algorithms. Sensitivity estimates at each pixel of the full FOV are generally required to perform the pixel-by-pixel subencoding matrix inversion of Equation (10). Ra and Rim describe the use of an in vivo sensitivity reference in the form of full-FOV component-coil images of the target image plane, manipulated in the reconstruction in such a way that the spin density divides out.⁹ The SENSE technique incorporates a different in vivo sensitivity calibration method in which full-FOV component coil images are divided by an additional full-FOV body coil image, and the quotient images are then subjected to several stages of interpolation, filtering, and thresholding.¹² Phantom sensitivity references can also, in principle, be used for subencoding reconstructions.

Figure 8 Coronal cardiac images from a 3D data set demonstrating the use of SMASH to increase temporal resolution at fixed spatial resolution (3D turbo field echo, TR 8.8 ms, TE 2.4 ms, in-plane spatial resolution $1.5\text{ mm} \times 1.5\text{ mm}$, with fat suppression, T_2 preparation, electrocardiogram triggering, and navigator gating/correction using a 6-element linear coil array on a 1.5 T Philips NT scanner). The reference image (sum of squares reconstruction) has an acquisition window of 200 ms per cardiac cycle. The twofold- and fourfold-accelerated SMASH images show progressively reduced motion blur and improved visualization of the right coronary artery running near the midline of the images

Whereas the quality of SMASH reconstructions is governed by the ‘goodness’ of spatial harmonic fits, the principal algorithmic concern of subencoding reconstructions is the numerical stability of the inverse $\mathbf{C}^{-1}$. For $N_c > M$, the inverse may be implemented, for example, as a Moore–Penrose pseudoinverse, resulting in a least squares solution to the over-determined problem for each pixel. For $N_c = M$, a standard matrix inverse may be used. The use of a pixel-by-pixel inversion affords the advantage of fine regional control over the reconstruction: it does not, for example, require a global spatial harmonic fit. A disadvantage of the pixel-by-pixel approach, however, is that in regions of low actual or apparent coil sensitivity, the matrix $\mathbf{C}$ may be poorly conditioned, and error propagation through the inverse may amplify the effects both of noise and of sensitivity miscalibrations.

4.3 In Vivo Results

Image-domain subencoding techniques can be used for many of the same applications as were demonstrated with SMASH in Section 3.3. The resulting images will resemble accelerated SMASH images, with some particular differences in image artifacts and noise distribution resulting from the different approaches to sensitivity calibration and image reconstruction. In vivo SENSE images in the brain and the heart with two- to threefold accelerations have been presented.^{12,15} An in vivo sensitivity calibration method similar to that suggested by Ra and Rim has also been used by the SMASH group to obtain accelerated subencoding images for direct com-

parison with SMASH reconstructions of the same data sets. Figures 12 and 13 compare reference, SMASH, and subencoding images from contrast-enhanced angiography and real-time cardiac MR imaging studies.

5 A RECIPE FOR PRACTICAL PARALLEL IMAGING

The following is a list of essential elements needed for effective implementations of partially parallel imaging strategies such as SMASH or subencoding.

1. *rf coil array.* Arrays should be designed with overall dimensions appropriate to the desired FOV for imaging applications of interest. Inductive decoupling of array elements is helpful for improved SNR and for increased spatial selectivity of the sensitivity profiles, although some degree of coupling between array elements can generally be tolerated. The imaging system must be equipped with a sufficient number of receiver channels to allow simultaneous data acquisition in the various component coils of the array. Alternative data-reception schemes such as time-domain multiplexing may also be used.^{16,17}

2. *Sensitivity calibration.* Accurate coil sensitivity calibration is crucial for all parallel imaging techniques. A great deal of effort has been devoted over the years to the understanding and calibration of gradient waveforms in MR scanners. Since parallel imaging strategies use rf coils in place of gradients for spatial encoding, it is not surprising that some

Figure 9 Noncontrast MR coronary angiograms obtained in reduced total scan time using SMASH (same basic sequence, coil array, and MR scanner as in Figure 8, with an acquisition window of 70 ms and an in-plane resolution of $0.7\text{ mm} \times 1.0\text{ mm}$). Double oblique image planes were planned along the major axis of the right coronary artery (RCA). (A) A 7.5 cm length of the native RCA in a healthy adult volunteer is seen in this high-resolution image. The 3D data set from which this image was taken was obtained during free breathing in a total of 11 min using a SMASH acceleration factor of two. (B) The RCA is interrupted by a region of signal dropout from a coronary stent in this local maximum intensity projection of a twofold-accelerated 3D SMASH image set (11 min free-breathing acquisition) in a patient with coronary artery disease

degree of analogous effort must go into the calibration of coil sensitivities.

3. *Scan planning.* After a target image plane and FOV have been selected, all that is required on most MR scanners to plan a SMASH or subencoding scan is a simple FOV reduction in the phase-encode direction. The need to perform spatial encoding with the rf coil array places some limitations on the choice of image plane position and orientation. For example, phase encoding must be performed along a direction in which the sensitivities of different array elements are sufficiently distinct. Substantial angulations between the image plane and the coil array are often possible (see, for example, the double-oblique images in Figures 9 and 13), though some penalty in SNR may be incurred.

4. *Image reconstruction.* Signal and image processing requirements are modest, but some capabilities for variable component coil signal combinations are required, whether in the MR scanner itself or in offline processors with access to

the raw MR signal data. Details of software and/or hardware implementations will depend upon which parallel reconstruction strategy is elected.

Occurring as they do on either side of the Fourier transform, the k -space and the image-domain reconstructions bear a theoretical kinship, but their practical specifications differ. The choice of reconstruction strategy may be influenced by a number of factors:

(a) *Ease of implementation.* SMASH uses a small number of weight factors (a minimum of one per component coil per spatial harmonic), and operates in k -space prior to Fourier transformation. Consequently, it is particularly amenable to in-line implementations in which the coil-encoded k -space data are generated as soon as each gradient-encoded data point is read out. By contrast, the large numbers of weight factors in subencoding (one per component coil per image pixel) provide finer pixel-by-pixel control at the expense of increased calibration and reconstruction time. In the future, compromises between these two extremes may be anticipated, using various extrapolation schemes.

(b) *Image artifacts.* In SMASH, residual aliasing artifacts result from errors in sensitivity calibration or spatial harmonic fitting.¹¹ In subencoding images, localized pixel-by-pixel artifacts are more commonly seen as a result of pixel-by-pixel errors in the coil sensitivity references. (These local artifacts may be accompanied by global aliasing artifacts when there are systematic errors in sensitivity calibration.) In some circumstances, however, both techniques can actually lead to artifact *reduction*. Not only can accelerated acquisitions reduce motion artifacts, but they have also been shown to reduce geometrical distortions in single-shot SMASH EPI images through reduced

Figure 10 Superposition of pixels (white squares) in an aliased image

$$I_j^{\text{fold}} = C_{j1} * \rho_1 + C_{j2} * \rho_2 + C_{j3} * \rho_3$$

Figure 11 Superposition of pixels (white squares) in an aliased or subencoded image set from an array, corresponding to Equation (7). The inversion of this equation, and hence the unraveling of pixel-by-pixel superpositions, forms the basis of the image-domain subencoding techniques

accumulation of phase discrepancies in the shortened acquisition time.

(c) *SNR*. The SNR in a partially parallel image reconstruction is a balance between coil-specific, reconstruction-specific, and sequence-specific effects. Theoretical and experimental studies of SNR in SMASH imaging have been reported.¹⁸ Generally speaking, both SMASH and subencoding techniques are bound by the well-known limit that SNR scales as the square root of the acquisition time for any given coil and sequence. With either class of technique, then, there is some expected loss of SNR compared with optimal combinations¹ of traditionally acquired full data sets in the same array, though parallel acquisitions may still show improved SNR when compared with sequential acquisitions using single surface coils spanning the same FOV. For certain imaging sequences, furthermore, some additional SNR beyond the square root limit may be recovered through reduced relaxation in the shortened acquisition times.

6 THE FUTURE OF PARALLEL MRI

Since the initial demonstration in 1997 of twofold-accelerated in vivo images using SMASH, new in vivo work has

shown up to fourfold increases in acquisition speed, and as much as eightfold improvements have been achieved in phantoms using specialized rf hardware.¹⁷ What future progress may be expected, and what are the key technical and methodological hurdles to further development?

Coil array design and rf sensitivity calibration top the list of developments that will be crucial for future improvements in parallel imaging, since array geometry and sensitivity characteristics determine the degree of spatial encoding which may be accomplished in any particular region of interest. The design of tailored arrays and the availability of increased numbers of receiver channels will greatly facilitate the optimization of image quality and SNR, and the maximization of achievable acceleration factors. In-line reconstruction hardware will be of benefit for real-time imaging applications. When the necessary weight factors are known in advance, the use of onboard analog signal combiners prior to digitization may even allow large ‘smart’ arrays to be interfaced to existing MR scanners with limited numbers of receivers. Methodological advances further in the future may also allow a return to the principle of massively parallel imaging. The potential gains of massively parallel imaging approaches are dramatic (they include the possibility of acquiring an entire image in a single echo, for example), but serious technological and theoretical hurdles remain to be overcome in areas such as electric decoupling of large arrays, massively parallel data reception, and SNR.

Figure 12 Maximum intensity projections of contrast-enhanced 3D MR angiograms of the abdominal aorta and renal arteries in a healthy adult volunteer (3D T_1 -weighted rf-spoiled gradient-echo imaging sequence, TE 1.5 ms, TR 7.0 ms, in-plane spatial resolution $2.7\text{ mm} \times 1.4\text{ mm}$, 6-element array, Philips NT scanner). The reference image set was obtained in a 23 s breath-hold following gadolinium injection, whereas the twofold accelerated data set used for SMASH and subencoding reconstruction was obtained in 11.5 s

In the meantime, clinical implementation of partially parallel imaging is possible now using existing arrays and receiver systems. Indeed, clinical studies in selected patient populations are now being initiated using parallel acquisition techniques. Particularly for applications with stringent requirements on imaging speed, parallel imaging can be a useful tool to enhance image quality, to improve imaging efficiency, and, in general, to overcome the acquisition speed limit in magnetic resonance imaging.

Spin Warp Data Acquisition

James M. S. Hutchison

University of Aberdeen, Aberdeen, UK

1 PRINCIPLES

1.1 Fourier Transform Methods

The Fourier transform (FT) group of imaging techniques derives from an idea presented by Kumar et al.¹ The fundamental idea is that the simple 1D projection is a Fourier transform of the *free induction signal* (FIS) as it evolves with time in the presence of a field gradient. If a second ‘dimension’ of time could be introduced in which the signal effectively evolved in the presence of another gradient at right angles to the first then a 2D Fourier transform of the signal, expressed as a function of ordinary time and ‘pseudotime’ (the second dimension), would produce a 2D image. In principle, one could extend the idea to many dimensions.

Now, higher dimensions of time do not exist, but a useful approximation can be obtained by appropriate subdivision of real time. For example, a TV video signal is a single valued function of real time alone, yet it can encode two spatial dimensions as well as time in the range of human activity. It does this by using a finite but adequate number of horizontal picture lines, and individual static image frames presented at a rate adequate to simulate movement. In FT imaging, the real-time evolution of the free induction signal in one field gradient is repeated many times, incrementing pseudotime between each repetition. With each repetition, a second field gradient is applied in such a way that its effect increases linearly with increasing pseudotime.

In the original method of Kumar et al.,¹ each new rf pulse and FIS sequence constitutes one increment of pseudotime. The second field gradient is applied immediately after the 90° pulse and immediately before the readout gradient, in which the signal evolves in real time. The second gradient has a constant amplitude, but its duration increases with each successive pulse–FIS sequence, that is, with the progress of pseudotime. The main disadvantage of the method is that the time between the 90° pulse and the observed signal varies, and hence the effects of transverse (spin–spin) relaxation and main field inhomogeneity increase with pseudotime, degrading the final image.

1.2 Spin Warp Imaging

If the second field gradient is applied for a fixed duration, but the amplitude varies linearly with the progress of pseudotime, then the above disadvantages are overcome. This is the principle of the *spin warp method*,² developed at the University of Aberdeen. The sequence of rf and gradient pulses is shown in Figure 1. We shall use a generalized coordinate system with axes s , r and c , representing the directions of the slice-selection

gradient G_s , the readout gradient G_r , and what is called the *phase encoding gradient*, G_c , respectively. G_c is then the gradient that varies with pseudotime. The selection gradient G_s , in combination with the shaped rf pulse, normally defines a slice in and close to the plane $s = 0$. In most imagers, the main field direction (z) is horizontal, along the head–foot axis of the patient, and y is vertical by convention. Thus, if we assign $x = r$, $z = s$, and $y = c$, a transaxial image will be produced. Sagittal or coronal images can be produced by interchanging the designations of the three gradients.

To understand why one may use a fixed duration, variable amplitude gradient, let us first consider the action of the ordinary readout gradient G_r on a spin packet (isochromat) at position (r, c) . The magnetization vector $\mathbf{M}$, viewed in the rotating frame, will rotate about the main field axis (z) by an angle Φ , and hence shift the phase of the induced signal by the same Φ , where

$$\Phi = \gamma \int_{t_0}^T r G_r dt = r \gamma \int G_r dt \quad (1)$$

which reduces to $\Phi = \gamma r G_r (T - t_0)$ for a constant gradient. Here T is real time and γ is the gyromagnetic ratio.

The gradient G_c also produces a phase shift over interval 2 in Figure 1, given by

$$\Phi_2 = \gamma \int_{(2)} c G_c dt = c \gamma \int_{(2)} G_c dt \quad (2)$$

but the requirement of the FT method is that this phase shift be

$$\Phi_2 = \gamma c G'_c T' \quad (3)$$

where T' is pseudotime and G'_c is the effective gradient in pseudotime. Hence,

$$\int_{(2)} G_c dt = G'_c T' \quad (4)$$

Figure 1 The spin warp imaging sequence

Figure 2 The pattern of free induction signals versus real time and pseudotime. t_e is the expected echo time

Since interval 2 is fixed, G_c must be proportional to T' . The shape of G_c is not critical; in practice, the rising and falling edges of the waveform may be slanted and rounded for ease of generation. It is also advantageous to employ both negative and positive G_c pulses, so that the range of T' is symmetrical about zero. In effect, this produces an 'echo' in pseudotime.

The individual amplitudes of the G_c pulses of duration t_0 then vary linearly with sequence number n according to the formula

$$\int_{(2)} G_c dt = G_0 [n - \frac{1}{2}(N+1)] t_0 \quad \text{for } n = 1, \dots, N \quad (5)$$

where G_0 is a constant. Figure 2 illustrates the pattern of FIS obtained as n is stepped through consecutive values, and when presented two-dimensionally like this, it can be seen that n does in fact behave as a pseudotime variable. For example, if t is held constant and n varied, we obtain a kind of spin echo in pseudotime, equivalent to interchanging the roles of G_r and G_c . It is as if we were using a readout gradient G_0 in the c direction. In fact, the image formation procedure is simply to carry out a two-dimensional Fourier transform of the free induction signal S as a function of real time t and pseudotime n . The spin density image can be expressed as P , a function of the r and c coordinates:

$$P(r, c) = k' \left| \int \int S(t, n) \exp(-ir\gamma G_r) \exp(-icn\gamma G_0) dt dn \right| \quad (6)$$

where k' is a suitable multiplying constant.

Note the modulus symbol around the expression for P . If the main field B_0 were completely homogeneous then the echo signal would be perfectly symmetrical about the echo time TE (ignoring T_2 decay), and its Fourier transform would have no imaginary components. In other words, all the frequencies present in the spin echo would have exactly the same phase, and we should get complete rephasing at the field echo time TE . In such an ideal case, there would be no need to include any modulus sign, since P would be real over the entire image plane. The phase of P contains information about the inhomogeneity of B_0 and chemical shift of the nuclei, but it contributes nothing to the density image, and is best discarded

by using only the amplitude (modulus) of P . In some types of image, such as inversion-recovery (IR), the sign of the NMR signal may be reversed in certain regions of the object, but the corresponding amplitude image will not show the reversal. This problem is discussed by Young et al.³ and Park et al.⁴

1.3 Phase Encoding and Frequency Encoding

An alternative approach to the action of spin warp imaging is to consider the pulse of the third gradient, G_c , introduced during interval 2, as producing a phase twist or 'warp' into each column (the c direction) of spins prior to collecting the FIS. It may be regarded as producing a phase encoding of the spin density before projection onto the r axis. In effect, the G_c pulse maximizes the response to a particular spatial frequency in the c direction, namely, that of the warp. It is for this reason that the c direction is usually referred to as the *phase-encoding direction*. The readout direction (r) is also commonly known as the *frequency-encoding direction*, after the essential function of a field gradient, namely that of causing the Larmor precession frequency to become a linear function of distance. The phase-encoding gradient G_c could also be regarded as encoding for 'pseudofrequency', that is, frequency on the scale of pseudotime.

1.4 k -Space

Almost all imaging techniques in use today employ the Fourier transform method in one form or another. The essential features of a single slice Fourier imaging technique are

1. a slice selection and spin excitation;
2. a readout gradient, during which the NMR signal is collected;
3. a phase-encoding gradient, applied between the excitation and the readout periods.

This classification of the separate functions of the three orthogonal gradients is adequate for the simpler FT imaging schemes, and is helpful in understanding the principles behind FT imaging. However, it is unnecessarily restrictive, and may have delayed the invention of some of the more esoteric sequences that have appeared in recent years. In particular, the functions of readout and phase encoding can be mixed, and may involve all three gradients (x , y , and z). The most convenient way to study the evolution of the spin system after excitation is by invoking reciprocal space or k -space as it is usually known.

k -space is really the Fourier transform domain of ordinary space.⁵ The relationship between the two is the same as that between (angular) frequency and time, which is probably a more familiar concept to many people. The k stands for the wavenumber, which is 2π times the number of wavelengths in unit distance. k -space has three components, as one might expect, so the vector k represents a single point in k -space, with components k_x , k_y , and k_z . In real space, it corresponds to a sine wave pattern of wavelength $\lambda = 2\pi/|k|$, with the direction of the normal to the wavefronts being the direction of k .

The action of the phase-encoding gradient pulse is such as to impose a 'twist' on a column of spins, so that their phases change linearly with distance along the c axis. In other words,

we have imposed a wave structure on the spins, with a characteristic wavelength λ , and hence a wavenumber k in the c direction. We have

$$\Phi(c) = \gamma c \int_0^T G_c dt \quad (7)$$

so that

$$k_c = \gamma \int_0^T G_c dt \quad (8)$$

Similar formulas are, of course, also true for the other two orthogonal components, so we can write a more general vector formula

$$\mathbf{k} = \gamma \int_0^T \mathbf{G} dt \quad (9)$$

This formula represents the point in $\mathbf{k}$ -space reached by the spin system at time T , assuming that the spins are all in phase at time $t = 0$. Generally speaking, it is unlikely that a given spin system will start out all in phase; if it has a particular phase distribution at time zero, this can be represented by a term $\mathbf{k}_0$ that may be added to the right-hand side of equation (9) as a constant of the integral.

By applying this formula to a field gradient sequence, we can trace out a path in $\mathbf{k}$ -space. The important parts of the path or paths are where the NMR signal is being collected for processing into an image. In a straightforward FT imaging procedure, the whole track in $\mathbf{k}$ -space should be a rectilinear scan, preferably with a square aspect ratio, since this implies equal spatial resolution along both axes.

The spin density distribution over the imaged region (the slice) can also be translated into a $\mathbf{k}$ -space distribution. We can then regard the NMR image as being the result of sampling this distribution via the sequence's track in $\mathbf{k}$ -space. Now the spin density distribution in real space is a real value (i.e., it has no imaginary part), so the true $\mathbf{k}$ -space map would be symmetrical about the origin. This means that it is only necessary to sample one half of $\mathbf{k}$ -space, since the other contains no extra information. In practice, this means that we could, say, collect only one side of our gradient or spin echo, while covering both negative and positive phase encoding. Alternatively, we might collect all the echo, but dispense with one half of the phase-encoding set. The latter is often used to cut down total collection time. However, unless the main field $\mathbf{B}_0$ is perfectly homogeneous, one must always cover slightly more than half of $\mathbf{k}$ -space, and use sophisticated computer algorithms to correct the results (see *Partial Fourier Acquisition in MRI*).

1.5 Transforming the Signal

So far, we have casually assumed that P is a continuous function of r and c , as implied by the integral representation. Obviously, n is not a continuous variable, but neither is t in practice. In order to process the signal digitally, S must be sampled M times at intervals of t_s , and our double integral becomes a double summation, which is just a two-dimensional

discrete Fourier transform (DFT). Thus, P is only defined at discrete points (k, l) of an $M \times N$ array

$$P(p, q) = k' \left| \sum_{m=1}^M \sum_{n=1}^N S(m, n) \times \exp\left(-\frac{2\pi i p m}{M}\right) \exp\left(-\frac{2\pi i q n}{N}\right) \right| \quad (10)$$

Each of these points, or *pixels*, corresponds to an element of volume in the original subject (the patient), known as a *voxel*. The image can be mapped onto a region of real space containing an array of $M \times N$ voxels (the object slice), whose overall dimensions are R in the readout direction (r) and C in the phase encoding direction (c), given by

$$R = \frac{2\pi}{\gamma G_r t_s}, \quad C = \frac{2\pi}{\gamma G_c} \quad (11)$$

It is important that R and C correspond to the intended dimensions of the frame of interest, so that the image geometry is correct.

2 PRACTICAL ASPECTS

For a detailed review of these, the reader should refer to the article by Johnson and Hutchison.⁶

2.1 Demodulating the Signal

After suitable amplification, the NMR free induction signal (FIS) is demodulated into two components in phase quadrature. In effect, these represent the magnetization components in the rotating frame, M_x' and M_y' . The (angular) rotation frequency ω_0 is that of the system reference oscillator, and would normally be the same as the actual Larmor precession frequency in the absence of field gradients. Full quadrature demodulation is necessary if we are to collect all the information in the FIS. Demodulation consists essentially of multiplication of the FIS by cosine and sine waves of the reference frequency, respectively, followed by low-pass filtering. Suppose the FIS from some spin packet is $A \sin(\omega t + \phi)$. The in-phase demodulator then multiplies the FIS by a reference signal $\cos \omega_0 t$, giving

$$S_R = \frac{1}{2} A \sin(\omega - \omega_0)t + \frac{1}{2} A \sin[(\omega - \omega_0)t + \phi] \quad (12)$$

while the quadrature one multiplies it by $\sin \omega_0 t$, giving

$$S_I = \frac{1}{2} A \cos(\omega - \omega_0)t - \frac{1}{2} A \cos[(\omega + \omega_0)t + \phi] \quad (13)$$

In each case, the low-pass filter removes the component at the sum frequency, leaving only the first term, that is, the difference frequency. Note that the two demodulated signals are now in quadrature, but both retain the phase term ϕ from the original FIS. The two signals, S_R and S_I , represent the components M_x' and M_y' of the magnetization vector in the rotating frame.

The multiplying device is variously known as a *phase-sensitive detector* (PSD), *double balanced modulator* (DBM), and *synchronous detector*, among other names. DBMs and PSDs are basically the same device, the difference lying in their application. A popular implementation as an integrated circuit is

Figure 3 Quadrature demodulator

available under the generic label '1496' (e.g., LM1496 and MC1496), and will function satisfactorily up to about 20 MHz.

When the Larmor frequency is higher than about 20 MHz, it may be necessary to make the receiver a *superheterodyne* system. Here the original FIS is shifted down in frequency to something more convenient, say about 10 MHz. This is again done using a balanced modulator driven by a *local oscillator*; the output is then the difference between the Larmor frequency and the local oscillator frequency, and is generally known as the *intermediate frequency* (IF). A further advantage of superheterodyne operation is that the working Larmor frequency can be altered simply by retuning the local oscillator; the main amplification and demodulation is carried out at the fixed intermediate frequency. The same principle can be used in reverse to produce the rf excitation pulses; the generation and shaping is done at the intermediate frequency, then shifted up to the Larmor frequency using the same local oscillator to drive another balanced modulator, except that this time the sum frequency is extracted.

Figure 3 is a block diagram of a typical quadrature demodulation system. It is essential that the reference signals sent to the two demodulators be 90° out of phase, and that the two channels have the same gain. As a general rule, the phase error should not exceed 1° , and the gain imbalance should not exceed 1%, otherwise image aliases will appear (see *Spin Warp Method: Artifacts*).

The low-pass filters do not simply remove components at and above the Larmor frequency f_0 . They must also act as *anti-aliasing filters* prior to digitizing the signals. For this purpose, they should have a well-defined cut-off frequency $f_{\max}$, corresponding to the spread of Larmor frequencies expected under the action of the readout gradient (from $f_0 - f_{\max}$ to $f_0 + f_{\max}$). When this signal is subsequently sampled for digitization, the Nyquist criterion states that the sampling rate f_s must be at least $2f_{\max}$. If $f_s < 2f_{\max}$ then a signal at a frequency $f > \frac{1}{2}f_s$ can still be within the filter's passband, but will appear, in its digitized form, to be at a lower frequency $f_s - f$, commonly referred to as an *alias*. The best gain versus frequency characteristic for an antialias filter is afforded by a maximally flat or *Butterworth* filter, which can be implemented using operational amplifiers configured as active filter building blocks.

A more versatile approach is to use *switched capacitor filters*; these are readily available as integrated circuits, ranging from basic two-pole building blocks to complete filters such as six-pole Butterworth or more sophisticated 'elliptic' filters. The big advantage of switched capacitor filters is that their cut-off frequency can be changed easily by changing the rate of the clock drive pulses. Conventionally, the clock rate is 50 times the required cut-off frequency, although there is nothing sacred about this ratio. Thus, a 10 kHz cut-off would need a 500 kHz clock. This feature is extremely useful when several different types of pulse sequence are being used in rapid succession, since the filters can be changed automatically under software control. Moreover, by using the same clock for both filters, their frequency responses change together and preserve the matching of the two channels.

In order to avoid the problems of matching the two demodulators and keeping the phases of their reference inputs exactly 90° apart, some workers⁷ have tried *offset carrier demodulation*. Figure 4 illustrates the method. The reference frequency f_c for the single demodulator is offset from the central Larmor frequency f_0 sufficiently to ensure that all NMR signal components lie on one side of it only. In the conventional setup, the second demodulator is needed to distinguish between positive and negative demodulated frequencies; in this case, however, all demodulated frequencies have the same sign, so it is unnecessary. The primary disadvantage is that the ADC must sample the signal much faster, i.e. at a rate of at least $2\Delta f_{\max}$, although only one ADC is required. Also, although the mirror frequency range (the second channel, as it is called) contains no NMR signals, it may still contain noise, so a good selective filter is required before the demodulator⁸ (see also *Whole Body Magnetic Resonance Spectrometers: All-Digital Transmit/Receive Systems*).

One rather important point to consider is how much gain should be applied to the FIS before it is presented to the demodulators. In theory, the maximum FIS should occur when all the spins in the selected slice are in phase, that is, when all the gradient integrals are zero. For a spin echo sequence, this should happen at the 'official' spin echo time, and when the phase-encoding gradient is zero. The peak signal is that due to all the spins in the slice, and may be estimated from the slice volume and the mean proton density. We shall denote this largest signal, as presented to the demodulators, by $S_{\max}$. Ideally, the whole receiver chain should behave linearly towards any signals up to an amplitude of $S_{\max}$. In the case of a field echo, main field inhomogeneity will normally prevent the spins all coming into phase at one time, thus reducing $S_{\max}$ and making

Figure 4 Spectral diagram illustrating the offset carrier method of signal acquisition

the job of signal acquisition easier. This is one of the few cases where lack of field homogeneity is an advantage! Some experimental groups^{9,10} have tried to overcome this problem by deliberately imposing a nonlinear distribution of phase on the precessing spins, by the use of higher order field gradients. Although the method works in principle, it requires the installation of one or more sets of additional windings to create these higher order fields. Some method that could use the existing hardware would be much more acceptable.

It is also important that the overall receiver gain does not change over the duration of a scan. Nevertheless, it is desirable to adjust the gain prior to each scan to make allowances for changes in slice width, pixel size, rf coil sensitivity, and so on. In some commercial imagers, a short dummy run is carried out, covering the middle range of phase encoding steps, where the conditions likely to produce $S_{\max}$ occur. Then the appropriate gain setting is selected automatically and the full scan carried out. This sophisticated procedure should not be confused with the so-called *automatic gain control* (AGC) incorporated into most radio receivers. AGC simply adjusts the gain so that the mean rf signal level at the detector remains fairly constant, which is not what we require. It should also be noted that many of the simpler electronic gain control circuits are not particularly stable when removed from the stabilizing influence of the AGC feedback loop. Gain control circuits suitable for imager use need rather careful design.

2.2 Signal Digitization

The two low-frequency signals S_R and S_I emanating from the demodulator and filter must be sampled at intervals of t_s and each converted to digital form by an analog-to-digital converter (ADC). For the simple single slice imaging sequences, a digitization rate of 10 kHz ($t_s = 100 \mu s$) is adequate. However, most of the FAST sequences and the majority of multislice sequences require much faster conversion, perhaps up to 100 kHz. It is essential that both signal channels be sampled simultaneously, since any delay between sampling one channel and the other is equivalent to a phase error, and will give rise to image aliases.

Probably the single most important consideration in choosing an ADC is the wordlength, or resolution in bits. This sets the dynamic range of the signal that the ADC can handle. Obviously, if the signal is too large, it cannot be represented by the number of bits available, and most ADCs will simply output the maximum possible number (all bits = 1) if the signal is too large, or all bits = 0 if the signal is too negative. The results of such 'clipping' on the image are described in *Spin Warp Method: Artifacts*.

If the signal is too small, the ADC can only choose the nearest discrete level, so that we can expect an error of up to half the value of the least significant bit (LSB). Supposing that our signal is a low-level sine wave, the digitized version will be chopped up into discrete levels, resulting in a staircase-like waveform. Any attempt to Fourier transform this will result in the appearance of unwanted harmonics. This type of error is known as *quantization noise*, and, because of its tendency to be structured and signal-dependent instead of random, it can give rise to structured noise on the final image. Quantization noise can be rendered much less troublesome by introducing *dither* on the signal, that is, an extra signal with an amplitude

Figure 5 ADC performance as a function of input RMS noise level in LSBs: (a) excess output noise; (b) 'structured' quantization noise

of about $\frac{1}{2}$ LSB, which does not clash with the wanted signal. It happens that the best dither is provided by white noise, which is normally present on the signal anyway. Figure 5 shows the effects of increasing the level of random noise on the signal. In theory, quantization noise imposes an error whose RMS amplitude is $\frac{1}{12}$ LSB. Once the input noise exceeds this amount, the staircase structuring is fairly well masked, and when the input noise reaches $\frac{1}{2}$ LSB (RMS), the extra noise produced by the digitization process is negligible.

Effects similar to those of quantization noise can be produced by nonlinearity in the ADC, except that they are not reduced by white noise dither. In bad cases, harmonics would be generated, and show up as aliases on an image. In practice, the standard linearity of $\pm \frac{1}{2}$ LSB is quite adequate for imaging work. This is in contrast to spectroscopy, where even tiny levels of harmonics are manifest as unreal spectral lines.

If the entire field of view were filled with active spins and the main field B_0 was perfectly uniform, the NMR signal would be concentrated so that it occurred entirely within one ADC sample. Then, for example, if the image signal-to-noise ratio S/N was 50:1 and the image matrix 256×256 , the peak S/N should be 12 800:1. Given that the noise should be equivalent to about 1 LSB, we can see that the ADC needs at least 15-bit resolution (32 768 levels) to fit this signal in, whether it be positive or negative. However, taking account of various mitigating factors, such as imperfect field homogeneity and the improbability of ever filling the entire field with spins, we find in practice that, for 2D imaging, a 12-bit ADC is generally adequate. These are standard commercial items, available with a range of conversion times from $100 \mu s$ down to less than $2 \mu s$. The price is almost inversely proportional to the conversion time.

The most severe demands on dynamic range are made by 3D imaging techniques. Here it may be necessary to employ 16-bit ADCs to accommodate the full range of signal amplitudes. Such high-resolution ADCs have been developed recently as part of the 'digital audio' revolution, but the fastest conversion time is limited to about $10\ \mu\text{s}$. To get the full advantage of a 16-bit ADC, very careful circuit design and layout is needed to avoid pickup of spurious signals. The full-scale input for such an ADC would typically be 10 V peak-to-peak, so that one LSB represents a mere $150\ \mu\text{V}$, a signal that cannot be seen on most oscilloscopes!

A different approach to the problem of wide dynamic range is the recent appearance of a device known as a *floating point ADC*. The first stage of conversion consists of changing the gain of a precision preamplifier in steps of two until the signal is within the range of the actual ADC. The output then consists of an exponent denoting the chosen amplifier gain, and a mantissa representing the ADC output. Using a 12-bit mantissa (i.e., a 12-bit actual ADC) and a 3-bit exponent, a dynamic range equivalent to 20 bits (one million to one) can be achieved.

Spin Warp Method: Artifacts

James M. S. Hutchison

University of Aberdeen, Aberdeen, UK

1 INTRODUCTION

In imaging technology, an artifact is a feature appearing on the image which does not correspond to the properties of the subject in the corresponding region. An artifact may arise from the equipment itself, from some unwanted interaction between the subject and the imaging equipment, or from an external cause. In NMR imaging, the artifact may be manifest as a local error in the parameter(s) being imaged, or as a feature displaced from its supposed 'correct' position. This second type of artifact is commonly known as an 'alias', particularly if it is fairly discrete and has some recognizable geometric similarity to the true image.

It should be expected that anything which distorts or changes the main magnetic field will cause artifacts. Temporal variations of the magnetic field also cause artifacts. These variations often arise in resistive magnets from instability of the power supply, or temperature changes in the magnet and/or its connecting leads. Superconducting magnets are much less prone to such variation, although movement of large ferromagnetic objects (e.g. trolleys, elevators) near the imager can affect the field. Random field variation over the timescale of the data collection for one image will tend to give a smearing artifact in the phase-encoding direction.

2 DISCRETE ALIASES

Discrete aliases are most often produced from misplacing of the patient, or choosing an object frame size which is too small, so that the patient overlaps the sides. In the spin warp method, this will cause image wrap around, either in the phase-encoding or the frequency-coding direction. This is more serious when the patient overlaps the frame in the phase-encoding direction, since there is no way to prevent wrap around except by repositioning. However, if the total extent of the patient section is less than that of the frame, the image can be 'unwrapped' quite easily; an example is shown in Figure 1. Wrap-around aliasing in the frequency-coding direction can be controlled either by the use of a sharp cutoff low-pass filter following the demodulators, or by oversampling the free induction signal. The former attempts to remove NMR signals the precession frequencies of which are too far from the central reference frequency, i.e. those which arise from tissues too far off-center in the readout gradient. Demodulated signals whose frequency f_m is more than half the sampling rate f_s of the analog-to-digital converter (ADC) become aliased to a new, lower frequency of $f_s - f_m$. Oversampling the ADC, say at twice the original rate, is a more satisfactory solution, although it is then necessary to FT twice as many points. The result is a double-width image frame of which only the central half is relevant.

Discrete aliases of different types arise from anything in the subject which changes in a regular cyclic manner, particularly if its frequency is harmonically related to the imaging sequence's basic repetition rate (TR). Heart motion and relaxed breathing are the main causes of such artifacts. Figure 2 shows discrete aliases of the anterior abdominal wall, caused by regular breathing motion.

Irregular motion, such as fidgeting by the patient, causes a more featureless smear in the phase-encoding direction. The extent of the smear is usually much greater than that of the patient's movement. It can also be caused by faulty cushioning, which slowly sinks under the weight of the patient during a

Figure 1 (a) Vertical image 'wrap around' shown on a transaxial head section. (b) Image unwrapped by postprocessing

Figure 2 A sagittal abdominal section, showing regular aliases of the anterior abdominal wall, caused by regular breathing motion

scan, even though the patient is well behaved. In many ways, irregular patient motion produces artifacts which are very similar to those due to field instability.

3 FLOW

Blood flow in major vessels and the heart can give rise to a number of different artifacts in normal imaging. Many of the effects of flow have been put to good use in flow imaging and measurement techniques. Briefly, constant flow tends to produce only changes of intensity; for example, saturation recovery (SR) images show brightening of flowing blood due to refreshment of spins within the slice in the time between consecutive rf pulses (TR).

On the other hand, pulsatile flow, such as that in arteries and the chambers of the heart, produces aliases similar to those due to cyclic motion. Figure 3 shows a transaxial thoracic section taken with an SR 200 sequence, where the heart rate was almost exactly one-third of the NMR pulse rate. Discrete aliases of the aorta and other blood-filled structures can be seen displaced vertically (the phase-encoding direction) by one-third of the full image frame height. Aliases of this nature may be interesting, but they can be very confusing in clinical routine, since they can occur within the boundary of the body and be wrongly interpreted.

4 CHEMICAL SHIFT ARTIFACTS

In high-field imagers, the chemical shift between water and fat may cause the 'water' and 'fat' images to be slightly displaced from each other in the frequency-coding direction. At 1.5 T, the two Larmor frequencies differ by about 200 Hz, equivalent to several pixels of shift. Clinically, this can be very confusing and is wide open to misinterpretation. Examples include kidneys displaced relative to perinephric fat, apparent displacement of intervertebral discs, the optic nerve relative to postorbital fat, and so on. Similar but less predictable positional shifts can occur from magnetic susceptibility effects. In particular, gas pockets within the body can produce nearby field changes of the same order of magnitude as chemical shift, with consequent distortion of the image. Both effects can also occur in the slice-selection direction; thus the 'water' and 'fat' components may not even be in the same actual slice. The problems of these shifts constitute one of the few realistic arguments against the use of high fields for imaging.

In the spin warp method, this chemical shift also produces a substantial phase shift between the water and fat components at the time of the gradient echo. In fact, this is the basis of Dixon's method¹ for separating out the fat and water components. As an example, a gradient echo at 8 ms after the rf pulse will incur a phase difference of over 600° in a 1.5 T imager. Dixon's method requires two images in which the fat-water phase shift differs by 180° , and is usually achieved using spin echo sequences in which the 180° pulse is asymmetrically placed, rather than gradient echoes which produce too large an effect.

5 MACHINE-GENERATED ARTIFACTS

We come now to the set of machine-generated artifacts, which covers a very wide range, including machine-specific artifacts, i.e. those which are peculiar to one make and type of

Figure 3 Transaxial thoracic section from an SR 200 sequence, showing discrete aliases of the vessels around the heart

Figure 4 Vertical banding on a head image caused by severe RFI from an unstable oscillator

imager only. We shall ignore machine-specific artifacts here, and describe some of the commoner effects that may arise on any imager.

A common source of unwanted features on an image is rf interference (RFI) entering the signal receiver. RFI may arise from external sources or from components of the imager itself, such as the data-processing computer. If the source is a very stable single frequency close to the imager's reference frequency, it may result in a single bright dot on the image. Many radio transmitters exhibit the necessary frequency stability to produce such dot artifacts. If the source is slightly less stable, say varying by a few hertz, the dot will extend into a line in the phase-encoding direction. Further instability, or strong modulation of the source, may produce a wider band on the image (Figure 4). Slow drifting of the source frequency is manifest as changes in the position of the interference band on consecutive images. Transient interference from, for example, light switches, thermostats, or electric sparks, may produce large errors in one or two signal data values; the result is often a characteristic 'herringbone' pattern across the image. Many commercial imagers have facilities to detect such signal spikes on any one 'line' of data, and to repeat the acquisition of that line. Doing 257 pulse sequences (lines) instead of 256 is a negligible burden when compared with a spoiled image.

Spin echo images can suffer from what is known as a central 'zipper' artifact. The central line in the frequency-coding direction contains incorrect and apparently random intensity values, as shown in Figure 5. This is the image line corresponding to no phase encoding, and the spurious data arise from the FID following the 180° pulse overlapping into the echo signal acquisition window. This FID is not subject to phase encoding and so is the same for each sequence repetition. The effect can be reduced by the use of spoiler gradient pulses, or moved to the outer edge of the image by phase alter-

Figure 5 Central 'zipper' artifact resulting from breakthrough of a non-phase-encoded FID

nating the 180° pulses. Gradient echo (field echo) images do not suffer from this effect

Errors occurring in the signal processing circuits of the imager can also produce artifacts. Imbalance of the two channels of the quadrature detector, either in phase (deviation from 90°) or amplitude, will give ghost image aliases of the true image, mirrored about the center of the image frame; i.e. if the true image is at (x, y) , a faint ghost will occur at $(-x, -y)$.

Generally the NMR signal consists of a lot of low level signal not greatly exceeding noise level, and a few relatively large and short echo peaks. To accommodate both the low level signals and the peaks, the ADC must have a wide dynamic range. If the system gain is set too high, it may happen that the ADC

Figure 6 Image intensity distortion resulting from signal overload at the ADC

is overloaded on the largest of the peaks, resulting in truncation of the data value. The typical effect on an image is shown in Figure 6. The outer background level is no longer zero, nor even constant; edge ringing is more pronounced, and fringing may appear in the outer regions, arising from diffraction-type interference between the NMR signals and the effective truncation 'spike'.

This has necessarily been a brief summary of artifacts. For a detailed and comprehensive review of imaging artifacts the reader is recommended to study the paper by Henkelman and Bronskill.²

Spiral Scanning Imaging Techniques

Albert Macovski and Craig H. Meyer

Stanford University, CA, USA

1 INTRODUCTION

Unlike other imaging modalities, MRI sequentially collects imaging data in the Fourier domain, or k -space, rather than in object space. The format of k -space scanning is determined by the integral of the applied magnetic gradients. At any time during the readout interval, the position in k -space is given by the time integral of these gradient waveforms (see also *Image Formation Methods* and *Spin Warp Data Acquisition*). Within limits imposed by the gradient amplifiers, and the dB/dt limits based on neural stimulation, any gradient waveform can be used. A spiral format, starting at the center of k -space and spiraling outward, is a natural approach with a large number of performance advantages. These include minimal flow dephasing, rapid coverage of k -space, efficient utilization of the available gradient power, and a well-behaved impulse response in the presence of T_2 decay.

The entire region of interest in k -space can be covered in a single spiral scan. However, this would require very high power gradient amplifiers and would reduce the signal-to-noise ratio (S/N). We first discuss the basic interleaved spiral imaging technique and some of its properties. We then discuss

important applications, including coronary artery imaging, abdominal imaging, and fluoroscopy.

Spiral k -space trajectories were perhaps first mentioned as an alternative to Mansfield's original echo planar trajectory¹ by Likes.² Ljunggren³ independently mentioned spiral trajectories and pointed out that a spiral trajectory would lead to an isotropic impulse response in the presence of T_2 decay, as compared to the anisotropic impulse response of the echo planar trajectory. Ahn et al.⁴ published the first spiral images. They used a sequence that traced a spiral with constant angular velocity, and reconstructed the images using a convolution backprojection algorithm. At Stanford, we showed that a spiral with constant linear velocity in k -space is optimal from an S/N standpoint.⁵ In our spiral experiments we have tried to approach this ideal of constant linear velocity in k -space, subject to gradient rise-time constraints.^{5,6} We also studied interleaving and square-spiral imaging, which has the advantage of only requiring one-dimensional interpolation and a fast FT for reconstruction.⁵⁻⁷

2 INTERLEAVING

A spiral k -space trajectory can, in theory, be traversed in a single-shot mode, similar to the way in which echo planar trajectories have been successfully employed^{1,8-10} (see *Echo-Planar Imaging*). We have concentrated on interleaved spirals because they can be readily implemented on standard commercial scanners. A set of interleaved spiral k -space trajectories is shown in Figure 1. The principal advantage of interleaving is practical: to traverse N interleaved spirals after N excitations, the required gradient power drops by about $1/N^2$, the required data collection bandwidth drops by $1/N$, and the S/N goes up

Figure 1 (a) A fast interleaved spiral pulse sequence. There is a spectral-spatial excitation pulse for fat suppression followed by spiral readout gradients. (b) Interleaved spiral k -space trajectories. The first section of the readout gradients on the left traces out one of these interleaves, and the other interleaves are traced out on subsequent readouts by rotating the readout gradients with a hardware rotation board

by $\sqrt{N}$, as compared to a single-shot scan. Interleaving reduces the gradient power requirements to a degree that enables the images to be acquired using standard commercial systems. The gradient power advantage of interleaving is also important in light of studies that have shown that strong echo planar gradients can induce physiological effects.^{11,12} Using cardiac gating, interleaved spiral imaging appears to be well suited to breath-hold coronary artery imaging, which is one of the major applications of this technique.

3 SPIRAL GRADIENT GENERATION

The radius at any point on an Archimedean spiral is proportional to the cumulative angle traced out to that point. A spiral k -space trajectory is thus given by

$$\mathbf{k}(t) = A\tau(t)e^{i\omega\tau(t)} \quad (1)$$

where $\tau(t)$ is some function of time. Setting $\tau(t) = t$ leads to the constant angular velocity spiral of Ahn et al.,⁴ with $\mathbf{g}(t) = iA\omega t e^{i\omega t} \approx d\mathbf{k}/dt$. A constant angular velocity spiral is undesirable from an S/N standpoint, because more time is spent near the center of k -space than near the edge. Assuming that the readout time is held constant, one must weight the data unequally in the reconstruction, which reduces the S/N. When one is trying to complete the scan as quickly as possible, a constant angular velocity spiral is also undesirable, because the readout gradients only reach their maximum amplitude at the end of the scan. Setting $\tau(t) = \sqrt{t}$ leads to a constant linear velocity spiral (ignoring the singularity at the origin), with $\mathbf{g}(t) \approx i\frac{1}{2}A\omega \exp(i\omega\sqrt{t})$. Since $\mathbf{g}(t)$ is proportional to the k -space velocity, it is evident from this equation that the magnitude of the k -space velocity is constant. The $\sqrt{t}$ term appears in the equation for $\mathbf{k}(t)$, but not for $\mathbf{g}(t)$. Unfortunately, this gradient waveform is impossible to generate on a scanner, because it starts at full amplitude, and gradient subsystems have rise-time constraints.

To deal with gradient limitations we choose $\tau(t) = \sqrt{t}$, except where such a choice violates gradient rise-time constraints. The resulting gradient will be rise-time limited during the first part of the scan and then will be constant amplitude for the rest of the scan. The problem of generating a rise-time limited spiral has been studied in the context of two-dimensional selective excitation.^{13,14} These algorithms have been adapted to generate spirals under both rise-time and amplitude constraints. The gradients shown in Figure 1 were designed using this algorithm; they are rise-time limited for the first 5 ms of the scan and then will be constant amplitude for the remaining 12.5 ms. For a given field-of-view (FOV), increasing the number of interleaves allows the gradients to reach a given amplitude faster. For a given number of interleaves, decreasing the imaged FOV also has a similar effect. Each of these effectively reduces ω in equation (1). Note that the complex magnitude of the gradients is constrained to meet the rise-time and amplitude constraints, so that these constraints are not violated when the gradients are rotated during interleaving. For a non-interleaved spiral, some time savings can be achieved by optimizing the x and y axis gradients separately.

4 FLOW PROPERTIES

Spiral readouts have surprisingly good resistance to flow and motion artifacts. Some of the spiral advantages accrue from the fact that the scan begins at the k -space origin. Flow dephasing occurs where material moving along a magnetic gradient produces phase shifts. These are often sufficiently large to cause loss of signal within a voxel. When a scan starts at the k -space origin, it ensures that the low-frequency high-energy components will not have time to accrue any significant phase shift. Thus the spiral format does not exhibit drop-outs in regions of complex flow. This can be seen by studying the various gradient moments $M_n(t)$ as given by

$$M_n(t) = \int_0^t \tau^n G(\tau) d\tau \quad (2)$$

Echo planar gradients that collect all of k -space are known to be susceptible to flow-related dropouts and artifacts.^{15,16} With spirals, the center of k -space is collected at the start of the scan and thus with zero transverse moments of all orders. Also, the symmetrical nature of spiral scanning means that spiral readouts do not suffer from the oblique flow artifact that two-dimensional FT sequences do.¹⁷

Another advantage of spiral gradients is that the moments of all orders in a particular direction periodically return to zero together during the readout, thus further reducing flow-related dropouts. Figure 2 shows the first three x axis moments of the gradients shown in Figure 1. The zero crossing points of the zeroth moment (k_x) are nearly coincident with those of the first and second moments. (The first moment is related to velocity sensitivity and the second moment is related to acceleration sensitivity.) One benefit of this moment behavior is that there is no cumulative buildup of these moments during the scan. Another benefit is that the flow sensitivity is quite

Figure 2 The first three moments of the G_x shown in Figure 1. Each moment is normalized to have the same maximum magnitude on the plot. The solid line is the zeroth moment (i.e. k_x), the dashed line is the first moment, and the dotted line is the second moment. Note that all three moments return to near zero each time k_x returns to zero, which means that the gradients are relatively insensitive to motion during the scan

low in the direction perpendicular to the direction of flow, which is the important direction for resolving the edges of a vessel. (The flow sensitivity along the direction of flow is quite benign as well, being predominately a blur related to the distance a spin travels during the readout window.)

5 RECONSTRUCTION CONSIDERATIONS

Reconstructing spiral images is of course more complicated than reconstructing two-dimensional FT images. The collected data points do not, in general, fall on a two-dimensional grid and so some operations must be performed in addition to a fast FT (see also *Projection-Reconstruction in MRI*). We use a gridding algorithm related to algorithms first used in radio-astronomy.^{18–20} The basic idea of the algorithm is to convolve the density-compensated k -space data into a two-dimensional grid, perform a two-dimensional fast FT, and then to compensate for the image intensity variations introduced by the convolution operation. An outline of the algorithm is as follows:

1. Determine the receiver offset frequency Δf . One method for doing this is to collect a FID with no readout gradients and to determine the peak of the spectrum of this FID.
2. Multiply the data points by $\exp(i2\pi\Delta f t)$ to demodulate at the offset frequency determined in step (1).
3. Multiply the data points by $|g(t)| \cdot |\sin[\arg\{g(t)\} - \arg\{k(t)\}]|$ to compensate for the varying density of the data points in k -space. The first term in this equation compensates for the varying k -space velocity, and the second term compensates for the increased density of the spirals near the origin.
4. Convolve the data into the two-dimensional array. This is done by multiplying each density-compensated data point by a Kaiser-Bessel window a few grid points in width, evaluating the result at each grid point within the window, and adding the result into the array. An auxiliary array is used to keep track of the amount of energy put into each grid point, which is the product of the density-compensation factor and the Kaiser-Bessel function evaluation.
5. Normalize the energy in each grid point by dividing by the auxiliary array. If the density compensation of step (3) is done properly, this step results in only a minor correction.
6. Perform a complex two-dimensional fast FT.
7. Divide by the transform of the Kaiser-Bessel window to remove the apodization resulting from the convolution of step (4).
8. Take the magnitude of the result.

6 OFF-RESONANCE CONSIDERATIONS

One of the disadvantages of spiral imaging is that the impulse response off-resonance is broadened, instead of just shifted as in two-dimensional FT imaging^{7,21} (see also *Susceptibility Effects in Whole Body Experiments*). Also, spiral readout times are typically longer than two-dimensional FT readout times, which allows more time for phase accrual. Because of these factors, it is necessary to take steps to minimize the off-resonance artifacts. The steps include the following: (1) suppressing fat, because fat and water will not

simultaneously be in focus at 1.5 T; (2) designing the gradients to reach maximum gradient amplitude as quickly as possible; (3) using as many interleaves as possible for the application, because the blurring is related to the time it takes to reach a particular radius in k -space; and (4) reconstructing at the proper frequency for the region of interest. It is also possible to deblur spiral images in postprocessing, both with and without a phase map.²¹

The fat suppression in our sequence is provided by a spectral-spatial excitation pulse, i.e. a pulse with an oscillating gradient that is simultaneously selective in space and frequency.²²

The deblurring process referred to is based on the simple premise that, in each region of the object, there is a desired demodulation frequency based on the local magnetic field. To choose the correct frequency for each region we create a frequency map by subtracting two images taken at different echo times. From the resultant phase difference we compute the frequency error.

Motion between field map collection and imaging can reduce the effectiveness of the deblurring. We minimize this by rapidly collecting a low-resolution field map immediately before imaging. Alternatively, the field map collection can be eliminated entirely. In this method, a sequence of images is created using different demodulation frequencies. For each incremental region of the object, we sequence through the stored images to find the one which minimizes the imaginary component resulting from phase shift. This has produced significantly improved images.

7 SPIRAL SCAN VARIATIONS

7.1 Square Spirals

A ‘square’ spiral, as the name implies, consists of a sequence of expanding squares in k -space.⁵ With an ideal gradient system, the gradient waveforms would simply consist of a series of rectangular pulses alternating in polarity and alternating between the x and y axes, which are incremented in width following each cycle. The magnitude of such gradients is constant, again providing a constant velocity in k -space. The principal advantage of the square spirals is that the scan format forms a rectangular grid of samples, which can be rapidly reconstructed using the classical two-dimensional fast FT approach. In our practical implementations of square-spiral scanning, we replaced the ideal rectangular pulses with triangular and trapezoidal pulses, because of gradient rise-time constraints.^{6,7} The resulting trajectory is still a square spiral, but it is not quite constant velocity and one-dimensional interpolations are necessary before the two-dimensional fast FT is undertaken. The major disadvantage of practical square-spiral scanning is that it is less efficient than round-spiral scanning, because the average gradient amplitude is lower and because the unneeded corners of k -space are collected.

7.2 RARE Spirals

A recent improvement has provided an additional approach to the problem of inhomogeneity. It is based on the rapid ac-

Figure 3 (a) Initial part of a single-shot RARE spiral pulse sequence. (b) The k -space trajectory of the fourth spiral segment. The trajectory starts and ends at the origin to preserve the Carr–Purcell–Meiboom–Gill (CPMG) condition on which RARE depends. (Reproduced with permission of Dr John Pauly)

quisition with relaxation enhancement (RARE) sequence²³ which involves scanning different regions of k -space interspersed with a sequence of 180° refocusing pulses. This enables an acquisition time of the order of T_2 . The spiral version uses a sequence of concentric spiral sections each separated by a 180° refocusing pulse.²⁴ This improves both the S/N and the immunity to inhomogeneity. The spiral section at the origin determines the contrast, so it is chosen for the desired T_2 sensitivity. The remainder of the spiral sections are chosen to ensure a smooth frequency domain, with a resulting well-behaved impulse response. The gradient sequence and k -space representation are shown in Figure 3.

7.3 Fluoroscopy

MRI is, in one sense, particularly well adapted for use in fluoroscopy because of its lack of ionizing radiation. Unfortunately, dB/dt considerations and existing gradient systems make it very difficult to cover all of k space in a typical frame time with sufficient resolution. Using spiral techniques, however, interleaved formats can be derived which present an effective dynamic presentation to the observer. Two techniques are employed, both of which are based on the premise that the human visual system has limited acuity to objects in motion. Firstly, we use a sequence of interleaved spirals at the desired frame rate. These are combined so that each output frame includes the sum of an interleaved set, providing full resolution. In this way, some of k -space, including the origin, is updated every frame. For a smoother presentation we combine the interleaves in a weighted fashion to provide an improved temporal impulse response. A triangular weighting has proven effective in our experiments.²⁵

In addition, each interleaf can be structured so as to repeat fully the low spatial frequencies and interleave only the higher spatial frequencies.^{25,26} This is completely in accord with

known visual physiology and is being considered in the formulation of high definition television.²⁷ A representative interleaf is shown in Figure 4, demonstrating the repeated low frequencies and the interleaved high frequencies.

7.4 In-Out Spirals

In spin echo imaging it is advantageous to collect data on both sides of the spin echo. One approach to collecting both sides of a spin echo with spirals is the use of spiral-in/spiral-out trajectories. Any T_2 decay is opposite on each portion, thus

Figure 4 The k -space sampling for a variable-density spiral used for continuous fluoroscopic acquisition. The center of k -space is sampled more rapidly than the edges, to match the spatiotemporal properties of the human visual system

Figure 5 (a) A full echo T_2 -weighted spiral sequence. (b) One interleaf of the corresponding spiral-in/spiral-out k -space trajectory

providing first-order cancellation when the two sections are combined in the reconstruction. In addition, for some spiral-in/spiral-out formats the phase buildup due to inhomogeneity is opposite on each portion, resulting in a real frequency spectrum with mild cosine weighting. The gradient waveforms and k -space format are shown in Figure 5.

8 SPIRAL SCAN APPLICATIONS

8.1 Coronary Artery Imaging

Spiral scans enable the efficient imaging of a section in the myocardium containing the desired coronary vessel (see **Heart: Clinical Applications of MRI**). The interleaved spiral sequence used for this work is shown in Figure 1. It consists of a 15.5 ms spectral-spatial excitation pulse and 17.5 ms spiral readout gradients, followed by transverse gradients to return to the origin in k -space and a spoiler gradient along the z axis. The spectral-spatial pulse suppresses fat, while simultaneously selecting a slice; the spatial profile is Gaussian and the spectral profile is minimum-phase to minimize spectral dephasing during the pulse.²⁸ The readout gradients are designed to image a 20 cm FOV in 20 interleaves. The gradients shown correspond to one of the interleaves; the other interleaves are traced by rotating the readout gradients.

We used the fast spiral sequence shown in Figure 1 to image the coronary arteries of normal volunteers and patients. The images were acquired in 20-heartbeat breath-holds with 17.5 ms readout windows using a 13 cm receive-only surface coil positioned on the chest of the supine subjects. The acquired resolution was $1.08 \text{ mm} \times 1.08 \text{ mm}$ (186×186 pixels over 20.0 cm). The flip angle was 90° for the static images, and fat was suppressed using a spectral-spatial excitation pulse.

Figure 6 shows a right anterior oblique image of the right coronary artery of a normal volunteer. The slice was prescribed

to be tangent to the heart in the axial scout scans. Figure 7 shows an oblique axial, or Gruntzig, view of the left coronary artery of a normal volunteer. The left main coronary artery, the left anterior descending coronary artery (LAD) and several branches of the LAD are visible.

Other coronary artery studies done with spirals include movies and multiple-slice imaging. In the movie, each interleaf acquisition is repeated throughout the cardiac cycle. Complete images corresponding to each portion of the cycle are then assembled and presented in movie form. In multiple-slice ima-

Figure 6 A right anterior oblique image of the right coronary artery of a normal volunteer. The image was acquired during a single breath-hold using the pulse sequence shown in Figure 1

Figure 7 Oblique axial (Grüntzig) view of the left coronary artery of a normal volunteer. The left main coronary artery, left anterior descending coronary artery (LAD), and several diagonal branches of the LAD are visible. The image was acquired during a single breath-hold using the pulse sequence shown in Figure 1

ging, during diastole, interleaves from successive slices are acquired to provide a complete volume of the heart. Using fat and muscle suppression, the coronary vessels can be readily visualized.

Figure 8 Breath-hold spiral-in/spiral-out image of a patient with no visible pathology. This image was acquired using the sequence shown in Figure 5 and a four-coil phased array was used for signal reception, accounting for the variations in signal intensity across the image

Figure 9 Breath-hold T_1 -weighted interleaved spiral image of a normal volunteer

8.2 Abdominal Imaging

Abdominal imaging has been plagued by respiratory motion. Conventional T_2 -weighted sequences suffer from long imaging times, motion artifacts and low S/N. In recent years a number of high-speed, T_2 -weighted techniques have enabled abdominal imaging in a breath-holding interval (see also *Liver, Pancreas, Spleen, and Kidney MRI*). For the most part these techniques have required special gradient hardware or suffered from low SNR, low resolution, or image artifacts. The interleaved spiral sequence shown in Figure 5 enables high-speed imaging with T_2 -weighting. The preferred sequence uses 12 interleaves with $TR = 2000$ ms, 24 s scan time, and a 36 cm field-of-view, resulting in a 196×196 image. A representative breath-hold image is shown in Figure 8. Spiral acquisitions can also be used to produce T_1 -weighted images. Figure 9 shows a 256×256 breath-hold T_1 -weighted image.

1 INTRODUCTION

The only new component which we need to consider in this article, additional to the normal complement of experimental factors for NMR experiments, is the presence of a large fixed gradient, $\mathbf{G}$, in the magnetic flux-density, $\mathbf{B}$. Normally in high resolution spectrometers we have the presence of a high degree of homogeneity in the magnetic flux-density, the 'magnetic field', to the tune of say 1 in 10^9 , over a sample about 5 mm in diameter in a flux of about 10 T or more. In other words the field variation across the sample is of the order of $2 \times 10^{-6} \text{ T m}^{-1}$. In conventional imaging instruments a gradient is introduced which is of the order of 10^{-3} T m^{-1} . The sample size may be as large as 1 m in clinical instruments, and the Zeeman polarizing field, $\mathbf{B}$, about 1 T.

The magnitude of the gradient we shall be considering here on the other hand is in the region of 50 T m^{-1} for a basic polarizing Zeeman-field of about 5 T. In other words the value of the ratio of $\mathbf{G}$ to $\mathbf{B}$ is about 10 m^{-1} , whereas it is effectively zero in normal NMR spectroscopy, and about 10^{-3} m^{-1} in conventional imaging experiments. This large gradient is to be found at the edge of a super-conducting solenoid in the so called stray field (STRAFI).

The consequences in the spin-physics of using a large gradient turn out to be rather more wide-ranging than one might initially expect. The first effect, of course, is that the radio-frequency field, $\mathbf{B}_1$, excites only a very narrow slice of the sample, the so-called 'sensitive slice' of Samoilenko.¹ This is normally about $50 \mu\text{m}$ thick for protons – the exact value depending on the length of the pulse, the pulse-shape and the line-width, W , of the sample. The main advantage which accrues is that Hahn spin-echoes can be produced from almost *any* sample for any tip-angle, so that it becomes easy to image any small object even one which gives rise to broad

lines. Solids may now be visualized even if they contain quadrupolar nuclides, or are paramagnetic, albeit at a spatial resolution limited normally by the spectral line-width. Liquids, liquids in solids, and solids are simultaneously accessible. The attainable spatial resolution for protons is in the region of between $1\text{--}100 \mu\text{m}$ depending on the conditions.

An additional great advantage of the STRAFI-technique is that the effects of distortion of the image, caused by variations in susceptibility producing local variations of $\mathbf{B}$, are reduced in proportion to $\mathbf{G}$.^{2,3} There is no need with STRAFI-imaging to operate at low Zeeman-fields as in conventional imaging to avoid this effect.

Also, of course, in very large gradients, the effects of diffusion become increasingly important, so that very small diffusion-coefficients, of the order of $10^{-15} \text{ m}^2 \text{ s}^{-1}$, come within measuring range.^{4,5} Normally in experiments conducted with short pulses and with small pulse-gaps of the order of say $10 \mu\text{s}$ the effects of diffusion may be neglected on the first few echoes.

The topic of STRAFI-diffusion studies has been discussed recently by Geil.⁶ The concepts in STRAFI-imaging have been covered briefly by Randall,⁷ and both the theory and many applications have been reviewed.^{8,9}

2 THE MAGNETIC FLUX-DENSITY AND THE GRADIENT-STRENGTH

If one has a conventional spectrometer or imager, the easiest way to introduce a very large gradient is to move the area of NMR operation away from the central region of the magnet, where the field-homogeneity is very high and the field gradients are very low, to the stray field, alternatively referred to as the fringe-field.^{4,5} For super-conducting solenoids in conventional instruments the area of largest gradient is near the edge of the super-conducting coils. This was part of Samoilenko's original idea.¹ The spectrometer he employed was a Bruker MSL 300. The position used in the stray field was chosen to be that at which the normal ^{31}P frequency in the central field, 121 MHz, and its associated electronic hardware, could be used for protons in the fringe-field. At this spot the gradient was about 37.5 T m^{-1} and the corresponding field was 2.89 T.

Normally super-conducting solenoids as used in NMR spectrometers have a complex arrangement of coils which vary from one manufacturer and magnet to the next. It is sufficient for our illustrative purposes, however, to consider a simple solenoid consisting of a single uniformly wound cylinder of length, l , and radius r , in the limit where $l \gg r$, carrying a current I in $\mathbf{n}$ turns. The magnetic field, $\mathbf{B}_z$, at a point P on the z -axis (the cylinder axis) is given by

$$\mathbf{B}_z = 2\pi nI (\cos \phi - 1) = A(\cos \phi - 1)$$

where ϕ is the angle between the z -axis and a line from P to the end of the coil. On axis at the end of the coil, taken as $z = 0$, $\phi = 90$, so $\cos \phi = 0$, and

$$\mathbf{B}_{\text{stray}} = 2\pi nI = A$$

The field at the center of the solenoid is double this.

Figure 1 Variation of B (full line) and G (dotted line) with distance for a simple infinitely long cylindrical solenoid (see text). (Courtesy of Dr. A. R. Preston)

The maximum gradient $G_{\max}$ occurs at $z = 0$ and is given by

$$G_{\max} = 2\pi \frac{nI}{r} = \frac{A}{r}$$

So if $A = 1$ T, then $B_{\text{stray}} = 1$ T, at $z = 0$, and for $r = 10$ cm, $G_{\max} = 10 \text{ Tm}^{-1}$. At the center of the magnet, where G is zero, B_{center} is 2 T.

The functions $B(z)$ and $G(z)$ are shown in Figure 1. $B(z)$ is nearly linear at the edge of the solenoid, i.e., when $z = 0$.

The exact position of the excited slice may be chosen by selection of the resonance frequency, ν , (or the field B). Because of the cylindrical symmetry of the solenoid the slice is actually saucer-shaped. The ideal position for locating it occurs at a position P_{optimum} where the saucer is a nearly planar disc and shows negligible curvature for some way off the z -axis in the xy -plane.

The situation may be represented by Figure 2 in which lines of equi-potential are shown. These are normal to the z -axis for some distance into the xy -plane at positions far from the end of the solenoid. Inside the cylinder closer to the end, the lines become concave but far outside it the lines are convex. In between lies the nearly flat disc. In theory at

Figure 2 Lines of equi-potential for a horizontal solenoid showing concave and convex regions and their near cancellation at the edge of the solenoid resulting in a nearly flat disc (after Samoilenko)

great resolution the disc is never quite flat but if the curvature is sufficiently small, compared with the resolution, this is not a major factor in determining the optimum position for STRAFI-studies. P_{optimum} occurs near the position of maximum gradient.

The situation for commercial NMR spectrometers is more complicated than for the simple solenoid, since the superconducting solenoids are complex. As a consequence the literature contains a variety of magnetic characteristics depending on the exact details of the magnet designs, which are not generally revealed. Most of the values reported in the literature for STRAFI-studies are shown in Table 1.

The effect of r may be seen from the table in two instances: of the two spectrometers with $B_0 = 4.7$ T, the one with the smaller radius has the higher value for the STRAFI-gradient, G_s , and the same is true for the two spectrometers with $B_0 = 14.1$ T. We may see, however, that the gradient in the last case is lower than expected.

The MSL 300 systems (third entry) have STRAFI-resonance frequencies which are rather low, as can be seen from the table, since they utilize center-field ^{31}P electronic hardware for protons in the stray field.

The high field magnet with a central field of 19.7 T is the latest addition to the STRAFI-family of instruments. It is located at the National High Magnetic Field Laboratory (NHMFL) in Tallahassee, Florida.

The main STRAFI centers for imaging until now have been Moscow (MSL 300, Samoilenko), Karlsruhe (Bruker MSL 400, Zick and Samoilenko), Lisbon (MSL 300, Nunes), Surrey (Chemagnetics 400, McDonald), and London (Varian 4.7 T, 30 cm., Kinches and Randall). Each of the instruments used takes samples about 1 cm^3 and has a vertical solenoid, except the last which is designed for 5 cm^3 samples, and has a horizontal bore-system. In all systems except that at Surrey both the sample and the STRAFI-probe move as a unit, whereas in Surrey only the sample moves. Many landmark developments were made at Bruker GmbH, Rheinstetten: the extension of STRAFI-1D-imaging to 2- and 3-dimensions, FT-STRAFI-imaging and micro-imaging. Accounts of these appeared in various Bruker Reports, but fortunately now they are referred to in the open literature, notably in the excellent review of Newling and McDonald.⁹

It was not until recently that magnets were designed specifically for their gradients rather than for the homogeneity

Table 1 Typical values for the central field, $\mathbf{B}_0$, the stray field, $\mathbf{B}_s$, the stray field gradient, $\mathbf{G}_s$, and proton resonance frequencies

Central field $\mathbf{B}_0/\text{T}$	Center ^1H frequency ν/MHz	Bore r/mm	Stray Field $\mathbf{B}_s/\text{T}$	STRAFI frequency ν_s/MHz	Gradient $\mathbf{G}_s/\text{Tm}^{-1}$
4.7	200	400	1.86	79	9.0
4.7	200	300	2.61	111	12.0
7.05	300	89	2.94	125	37.5
9.4	400	89	5.52	235	58.5
14.1	600	89	9.66	411	52.9
14.1	600	54	8.9	380	90.0
19.6	833	32	11.2	477	75.7

of their central fields. A magnet with a very large gradient (200 Tm^{-1}), the product of two anti-Helmholtz coils, has been described for STRAFI-diffusometry. The field at the center of the coils is zero so a position off-center, where the field is 2 T and the gradient is 180 Tm^{-1} is used for the diffusion measurements.¹⁰ An ingenious design for a horizontal permanent magnet for STRAFI-work informally known as GARField (Gradient at right angles to field) has been described. The pole-pieces are shaped to give planes of constant $|\mathbf{B}|$ in the horizontal direction – the magnetic lines of force are approximately parallel and horizontal – but with a strong *ortho-normal* gradient. In this case $\mathbf{B}_1$ and $\mathbf{G}$ are parallel and vertical (with $\mathbf{B}$ at right angles), whereas in the conventional STRAFI-arrangement $\mathbf{B}$ and $\mathbf{G}$ are parallel (and $\mathbf{B}_1$ is at right angles). GARField operates at a field of 0.8 T and a gradient of 20 Tm^{-1} . $|\mathbf{B}|$ has a curvature of less than $\pm 5\text{ }\mu\text{m}$ over an area of $5 \times 5\text{ mm}$. The rf-coil is mounted underneath the sample which is placed on a glass cover slip. The rf-assembly may be adjusted to lie in the horizontal plane to better than $10\text{ }\mu\text{m}$. GARField is ideal for the study of thin films and coatings at high spatial resolution.¹¹

Another type of system which operates in strong gradients is the MOUSE (Mobile Universal Surface Explorer). It is an example of a portable, ‘inside-out’ NMR system. The system has a very small permanent magnet which is applied externally to an object of interest. The magnet consists of two parallel opposed permanent magnets joined by a yoke at one end. At the other end an rf-solenoidal surface-coil is placed in the gap between the two magnets, so that the static field $\mathbf{B}$ and $\mathbf{B}_1$ are approximately at right angles.¹² A major difference from the super-conducting magnet systems is in the use of surface-coils which give a variation of $\mathbf{B}_1$ across the sample. The arrangement is similar to the NMR equipment used for oil well logging. Although the fields and gradients of both of these systems are lower than for the STRAFI-systems utilizing super-conducting solenoids, there is a similarity in the ratio $\mathbf{G}/\mathbf{B}_s$, which is about 10 m^{-1} in all three cases.

3 STRAFI-WORK IN THE SENSITIVE SLICE

The *location of the sensitive slice* can be chosen for a given nucleus by an appropriate choice of the resonance frequency, ν , according to the basic resonance equation, which is simply given by

$$2\pi\nu = \gamma\mathbf{B} \quad (1)$$

where γ is the gyromagnetic ratio. Alternatively of course, if $\mathbf{B}$ can be varied, one can operate at fixed frequency and change

$\mathbf{B}$. We neglect for the moment considerations of the screening constant, σ , the coupling constants, $\mathbf{J}$ and $\mathbf{D}$, between the nuclear magnetic dipoles, paramagnetic effects, and the electric quadrupole coupling constant, χ . Additionally we may note in passing that in neglecting $\mathbf{D}$ and paramagnetic dipoles, we shall be ignoring the complications of the *dipolar field*, which is alternatively but less satisfactorily referred to as the *demagnetizing field*. In other words, we shall adopt, initially at least, what is called the high field approximation: which assumes that the *induced* field due to the polarized dipoles can be neglected relative to $\mathbf{B}$.

It is interesting to compare the positions of the sensitive slices for two different types of nuclides which have different gyro-magnetic ratios. The first such pair to be considered was ^1H and ^{19}F at a constant frequency.¹³

The separation, $\mathbf{d}$, of the sensitive planes is easily calculated for a fixed resonance frequency, ω_s , and is

$$\mathbf{d} = \frac{\omega_s}{\mathbf{G}_s} [\gamma_F^{-1} - \gamma_H^{-1}] \quad (2)$$

in which γ is the gyro-magnetic ratio and ω_s is the STRAFI-frequency in angular units. The value of $\mathbf{d}$ depends on the ratio of $\mathbf{G}_s$ to $\mathbf{B}_s$ for the instrument being considered. We may refer to this separation as the γ -shift by analogy with the chemical shift. Shift effects may be included in equations (1) and (2) by the introduction of the screening constant: it is normally too small, however, to affect the experiment. For paramagnetic compounds on the other hand large shift effects due to hyperfine interactions may become significant. We have observed one such effect: the ^{31}P -sensitive plane and therefore the ^{31}P 1-D profile of cobaltous phosphate is shifted relative to the profile of calcium phosphate because of a hyperfine shift of 1.5 MHz. Even in diamagnetic compounds we may expect that in the case of heavy atoms which have very large chemical shifts, chemical shift displacements may be observed in images.

For the MSL 300, $\mathbf{d}$ is about 4.9 mm for the ^1H - ^{19}F pair, whereas on the lower field Varian system at Queen Mary, University of London, it is 13.6 mm.

For any other pair of nuclides which have values of γ which are nearly equal the γ -shift is smaller and the images of the nuclides may overlap (see later). Examples are: ^7Li , ^{11}B and ^{31}P ; ^{23}Na and ^{27}Al (and ^{51}V); ^{63}Cu and ^{65}Cu ; ^{75}As and ^{115}In . In these cases the experiment cannot distinguish between the signals from the different nuclides in the overlapping region of the images, except by means of differential relaxation weighting. This overlap-factor may prove to be one of the main limitations of the STRAFI-method for multinuclear situations.

The **thickness of the sensitive slice**, Δ , depends on two factors: the width, P , of the excitation pulse, or more correctly the pulse-shape, and the width, W , of the transition or NMR line, or again the shape of the resonance. It is given simply by the convolution of the two functions in the frequency domain.^{7,14}

$$\Delta = P * W \quad (3)$$

The easiest case for consideration is the uncommon one in which the pulse has a sinc form in the time-domain and consequently gives a simple square or top-hat shape in the frequency-domain for P . Lines whose centers lie outside this excitation envelope but which overlap it, will contribute to the magnetization. The width, W , of the transition is given by the ‘homogeneous’ line-shape and the relaxation time, T_2 , for liquids. If we introduce considerations of screening constants, and the dipolar and quadrupolar interactions, the appropriate line-shape for a solid will depend on the nature of the solid: for a powder the ‘heterogeneous’ powder line-shape is relevant.

The effect of W on the thickness of the excited slice, and hence on the initial magnetization, was shown by a comparison of the deuterium signals from heavy ice and heavy water: the former was about 3 times larger than the latter because of the line-width effect, despite the much smaller T_2 for the solid.

The **magnetization of the sensitive slice** is complex: it is the sum, or rather the integral, of the magnetizations across the slice. These differ because the field at each position varies across the slice. In other words there is a large field-offset which is about 5×10^{-4} T for a $100 \mu\text{m}$ slice and a gradient of 50 Tm^{-1} . In frequency terms this is 0.02 MHz , or 20 kHz for protons. The consequence of this large offset for STRAFI-studies is that the tip-angle varies across the slice: if it is 90° at the slice-center it is much different at the extremes of the slice. The observed total magnetization may therefore be viewed as a superposition of the responses to a varying tip-angle and phase.

In accurate simulations of the response of the system to the pulses, therefore, it is necessary to sum the calculations across the slice. Otherwise the alternative is to use the ‘delta approximation’ in which it is assumed that the tip-angle is constant.

For quadrupolar samples the electric quadrupolar interaction can be large, much larger than the dipolar interactions, and may become the dominant factor in the determination of Δ .¹⁵ This is shown in the Figure 3: at low values of the electric quadrupolar coupling constant, χ (or C_p), the pulse duration and shape are the main factors but above about $C_p = 1 \text{ MHz}$, W dominates.

3.1 Calibration of the Gradient Strength

Equation 2 gives a method for the easy calibration of the STRAFI-gradient strength, G_s , by accurate measurement of d since all other terms in the equation are known to a high order of accuracy.¹⁶ A good alternative method is by field-profiling, that is by simply measuring the resonance frequency as a function of position. One problem with this is that the frequency range to be covered is very high and the probe needs to tuneable over the desired range. Both methods have the advantage that they are ‘primary methods’ and do not need knowledge of a parameter determined elsewhere, such as a

Figure 3 The slice-thickness as a function of pulse-duration and strength of the B_1 -field, ν_{RF} , and $C_q(\chi)$ for a spin with $I = 3/2$, at a constant tip-angle of 90° . The pulse-delay, τ , is $50 \mu\text{s}$ for sequence 4 with two pulses in quadrature

diffusion constant in the diffusion method of calibration, which can be regarded as a secondary method and requires careful matching of experimental conditions, such as the temperature of the both sample and a standard substance.

Generally the manufacturer’s calculated field-plots are sufficiently good and give accurate enough values for the gradient for most purposes. In general the most accurate calibration is required only for measurements of diffusion-constants to a high order of accuracy.

3.2 Spin-Echoes in STRAFI

STRAFI-experiments are invariably conducted with spin-echoes in order to overcome the effects of the large gradient: collection of the initial FID with present electronics is not possible, since the dead-time is normally too short. The echo-width is determined mainly by the dominant interaction which is the gradient, and is very narrow.

Hahn’s original experiments, reported in 1950, were conducted with 90 degree pulses which had no specific phase relation to each other, and in magnetic fields which were not very homogeneous. The samples were restricted to protons in liquids, except for one sample, paraffin.¹⁷ In other words the main de-focussing agency was the inhomogeneity, and neither a dipolar interaction nor a quadrupolar. This is the general sense in which we shall use the term Hahn-echo for STRAFI-echoes since even for dipolar solids the main term is the STRAFI-gradient. In Hahn’s case the inhomogeneity was not so great that chemical shift effects were obscured unlike the situation in most STRAFI-experiments.

The basic two-pulse Hahn sequence (sequence 1) was $90 - \tau - 90$, and this led to an echo at time 2τ . The echo is caused by a re-focussing of the magnetization vectors. These are diverging after the first pulse, since different spin-packets experience different magnetic fields because of the natural width of the line and the different fields, B_0 , across the sample caused by the inhomogeneity. The explanation of the re-focussing after the second pulse, which was ascribed by Hahn to Purcell, was by a motion of the spin vectors in

the rotating frame, which had the shape of a Figure 8, the so-called eight-ball of pool. In fact *any* two pulses, not only those with tip-angles of 90 degrees, will give some re-focussing, the amount depending on the value of the tip-angle, α : Hahn's original 90 degree pulses re-focus only half the magnetization.

The sequence $90 - \tau - 180$ (sequence 2), on the other hand, will re-focus *all* the magnetization, apart from any lost because of relaxation. Moreover the re-focussing in this case is easier to represent and to visualize than the eight-ball so that for many *it* has become known as the Hahn sequence. It was actually Carr and Purcell who proposed it: for the measurement of T_2 by observation of the decay of the echo-amplitudes as a function of τ .¹⁸ The field inhomogeneities, which give rise to an apparently shortened T_2 , referred to as T_2^* , are exactly re-focussed at the top of each echo, so the echo-tops decay according to the true T_2 .

Hahn also used more than just two pulses and produced echo-trains. He had, however, no control over the phase of the pulses. He generated stimulated echoes as well as direct echoes and separated them by using more than one value of τ between the pulses.

Later in 1958 Solomon, in a little noted piece of work, produced echoes from a quadrupolar solid, nowadays referred to as quadrupolar echoes.¹⁹ The sequence used was

$$\alpha_x - \tau - \alpha_x \quad (\text{sequence 3})$$

An important breakthrough was made for dipolar solids in 1965 by Powles and Mansfield with two sequences which differed in the phases, an advance on Hahn's original work²⁰

$$90_x - \tau - 90_y \quad (\text{sequence 4})$$

and the in-phase sequence

$$90_x - \tau - 90_x \quad (\text{sequence 5})$$

In sequence 4 the pulses are said to be in quadrature, so this sequence is called a quadrature sequence, whereas sequence 5, which has no phase-change between the pulses is referred to as an in-phase sequence.

Sequence 4 produces the dipolar echo from dipolar solids, commonly referred to as the 'solid-echo', whereas sequence 5 did not. In view of the fact that the first echo from a solid sample was the quadrupolar echo observed by Solomon, we shall avoid using the term solid-echo and solid echo-sequence to refer and sequence 4.

It is an important feature of STRAFI-work in large gradients that *both* sequences 4 and 5 produce echoes from *either* solids or liquids.

Simulations with the GAMMA-platform (a suite of consistent NMR programs²¹) extended to STRAFI-calculations show this: see Figure 4. The spin-system is simply treated as spin-half dipolar. The calculations reproduce the different results of Powles and Mansfield when $\mathbf{G} = 0$ for the two sequences, but they show that at large values for $\mathbf{G}$ the quadrature and in-phase echoes are virtually indistinguishable. The explanation is simply that when $\mathbf{G}$ is large the effect of the dipolar term in the Hamiltonian is negligible in comparison with the gradient term, as noted earlier. This may be referred to as the high magnetic field-gradient approximation in which all terms in the Hamiltonian are smaller than the gradient term.²² Exceptions to this approximation so far noted are for interactions

which may be large, of the order of MHz, namely quadrupolar couplings and hyperfine interactions.

3.3 STRAFI-Echo-Shapes

STRAFI-echo-shapes differ from the shapes for the same pulse sequence in the absence of the gradient because of the effects of offset. For an assumed rectangular pulse-shape the echo-shapes for differing nominal tip-angles are shown in Figure 5 for sequence 4. These data have been computed by use of GAMMA-STRAFI which sums the echoes from each position in the sensitive slice: the number of subsystems was set at 2 per micron over 25 microns.²³ The effect of the gradient is easily seen for a tip-angle of 180 degrees. When $\mathbf{G} = 0$ one expects no echo, but the effect of the assumed gradient of 50 Tm^{-1} gives an echo which is zero only at its center: at either side of center the echo is finite and has opposite signs. Different echo-shapes are produced when the pulse-shape is changed from rectangular to sinc or Gaussian. These calculations give very accurate methods for the calibration of the tip-angle (see below).

3.4 Many Pulses: Long Echo-Trains

Both the Mansfield and the Waugh groups used many pulses in an extension of the quadrature Powles-Mansfield sequence:

$$90_x - (\tau - 90_y - \tau - \text{echo-})_n \quad (\text{sequence 7})$$

They observed that the echoes did not decay as T_2 but that the echo train was lengthened. The deduction that some line-narrowing had occurred was a most useful result for the spectroscopy of solids.^{24,25} The work developed into other sequences which produced even more line-narrowing.

In the case of sequence 7, a ready explanation at hand makes use of the concept of spin-locking. Strictly spin-locking is defined in the continuous wave limit, where the second pulse can be regarded as infinitely long. Then one may consider that at resonance the magnetization is locked in the xy -plane of the rotating frame. In this case the relaxation is not according to T_2 , but is referred to as T_1 in the rotating frame, and given the symbol, $T_{1\rho}$. This is longer than T_2 , so the line is narrower, and shorter than T_1 . In actual pulse-cases the extent of the spin-locking depends on the duty-cycle and is maximized when τ is short.

If there is no phase-change as in sequence 8

$$90_x - (\tau - 90_x - \tau - \text{echo-})_n \quad (\text{sequence 8})$$

then there is no spin-locking. Also some echoes are negative whereas all echoes from the quadrature sequence 8 are positive, see Figure 6. Both of these sequences are very useful in STRAFI-studies.

Figure 6 also shows the Hahn-nature of the STRAFI-echoes since echo-trains are obtained from both a solid and a liquid for each of the sequences 7 and 8.²⁶

Clearly the echoes from water cannot be classed as dipolar echoes, and the echoes produced by the in-phase sequence for the solid also are not dipolar in nature. All STRAFI-echoes are now classified therefore as Hahn spin-echoes.

Both sequences 7 and 8 have been considered theoretically by Bain and Randall using a density matrix treatment with and

Figure 4 Simulated Echoes using the GAMMA-STRAFI for a dipolar solid for each of the sequences 4 and 5 (in-phase and quadrature, here referred to as EVEN and ODD, respectively), as the gradient strength ($\Delta B/\Delta z$) increases. The system consisted of two protons set to resonance at 300 MHz with a dipolar coupling of 50 kHz. The pulses were rectangular with a duration of 10 μs and a τ -delay of 50 μs . A 2 kHz apodisation was applied and powder averaging was included in the calculation. The inset at top left reveals the absence of a dipolar echo and the emerging Hahn-echoes for the EVEN sequence, and the top-right inset shows the same region of critical gradient strengths where the dipolar and Hahn-echoes compete. (Courtesy of Dr. S. A. Smith)

Figure 5 GAMMA-STRAFI calculations of the shape of the first echo as a function of the tip-angle for the slice-center. Rectangular pulses were assumed for the quadrature sequence: $\nu = 300 \text{ MHz}$ and $G = 50 \text{ Tm}^{-1}$. A single proton system was assumed. SysLen is the length over which summation of the subsystems is made within the sensitive slice. The number of subsystems was set at 2 per micron. Notice the echo broadens as SysLen decreases: it will be maximum for the central subsystem. (Courtesy of Drs. P. Kinches and S. A. Smith)

without the gradient.²⁷ They showed that all echoes after the first are composite echoes, most of which are governed partly by T_1 (see later).

This T_1 -weighting is very useful for cases where T_1 is long, such as it frequently is for, say ^{15}N , ^{29}Si , and ^{31}P , particularly in solids. The idea is simply to collect the echo-tops, and sum all the values. This has been common in most STRAFI-experiments, but initially only for a modest number of echoes

up to about $n = 64$ or less. Recently the advantage of using very long echo-trains, with n in the region of thousands, has been pointed out, since large time-savings may be achieved. The effect is quite general. Published examples so far include solids containing ^2H , ^{14}N or ^{31}P .^{14,28,29} We should note that the technique, called Long Echo-Train Summation, LETS, should be applicable to spectroscopic studies in homogeneous fields for either solids or liquids. In these cases the whole of the

echo should be summed since Fourier transformation should then give the spectrum. The achievable spectral resolution, however, will be determined by τ since this limits the echo-sampling time.

3.5 Primary Hahn-Echoes: the Dipolar Field

STRAFI-work on solids has shown the many spin echoes, which we refer to as Primary echoes, are obtained also from just two pulses only³⁰ (Figure 7). This effect is due to non-linear effects and the breakdown of the high-field approximation, i.e., the induced dipolar field is not negligible. It is accounted for by the fact that the initial magnetization in the vector model forms a spiral in the rotating frame. This is just the large offset and variation in phase angle across the slice which we have discussed above.

This effect was first observed as long ago as 1974 for solid helium in modest gradients.³¹ The echoes continue to be referred to, rather misleadingly, as Multiple Spin-Echoes

Figure 6 Spatially separated echo-trains for the protons in a phantom consisting of poly(methyl methacrylate), PMMA, and water, for both the in-phase sequence 7 and the quadrature sequence 8 (here called EVEN and ODD respectively). The water-meniscus is clearly seen on the water image. Conditions were: $\nu = 123.4$ MHz; $G = 37.5$ Tm⁻¹; $t_p = 10$ μ s; $\tau = 25$ μ s; repetition time 1 s; number of sampled echoes = 32; 100 echo-trains accumulated

Figure 7 Multiple primary Hahn-echoes from protons in a sample of silicone rubber. Conditions were: $\nu = 123.4$ MHz; $t_p = 8$ μ s; $\tau = 7.7$ μ s; repetition time 10 ms

(MSEs). The sample was solid helium at first but the work was then extended to liquid helium. At the time it was forecast that the results would not be extended to other solids and liquids. The argument was that for solids the lines would be too broad and the relaxation times too short. Solid helium was thought to be a special case: the spectral lines are narrow because of an exchange interaction, peculiar to helium. Although liquids in general give narrow lines and have long relaxation times the reasoning was that because of diffusion effects, only one echo would be obtained.

Both of these arguments were shown subsequently not to be valid. Firstly, for liquids Bowtell et al.³² and Morris et al.³³ produced many echoes from just two pulses with modest gradients on conventional spectrometers, but it was not until 21 years after the first observation that the effect was experimentally generalized to all samples, solids as well as liquids, by STRAFI-experiments.³⁰ Primary Hahn Echoes are becoming fashionable in the imaging of liquids. Extension of this type of imaging to solids will require application of STRAFI-techniques. For STRAFI-cases in which many pulses are used it has been shown that the effects of the dipolar field are small so that the contribution of the MSEs to the STRAFI-echoes may be neglected.²⁹

It has been pointed out by Okibo et al. that sufficient relaxation delays must be used between repetitions of sequences 4 or 5, otherwise effectively the actual sequences are not simple two pulse due to a storage effect.³⁴

3.6 STRAFI-Relaxation

The relaxation behavior of the STRAFI echo-train is very complex even if diffusion is not included. The reason is that the total echo-train is the sum of the echo-trains of the isochromats at each position of the slice. For example if there is spin-locking, not only does the initial magnetization of one component of the train vary with the pulse-angle, α , but so also does the length of its echo-train. For example for $\alpha = 45^\circ$ the initial magnetization, M_{45} , is less than M_{90} for $\alpha = 90^\circ$, but the length of the train is longer, so that the two trains cross. All the other isochromats must be added in.²⁹ If long echo-trains are being observed then diffusion-effects should be considered, especially for liquids.

For either of the sequences 7 or 8 the first echo of the echo-train, whether a gradient is present or not, has only one coherence pathway and consequently its relaxation characteristics are governed by T_2 only (if the diffusion-term is small as it is for small values of τ). Consequently T_2 may be determined by arraying τ and observing the first echo as in Hahn's original experiments. The second echo formed by the application of three pulses, however, has two coherence pathways and the T_2 -contribution is only 1/2, the rest being T_1 . (This may be contrasted with the CPMG case where the pulses after the first 90° have $\alpha = 180^\circ$ and there is no T_1 -contribution).

The number of coherence pathways for the $(n + 1)$ th echo is the sum of the coefficients of s^{n-1} and s^n in the expansion of the generating function

$$(1 + s + s^2)^n = \frac{(1 - s^3)^n}{(1 - s)^n}$$

The number of pathways increases from the first to the tenth echo in the sequence

$$1, 2, 5, 13, 35, 96, 267, 750, 2123, 6049$$

The second echo for sequence 7 has an intensity of 3/2 relative to the intensity of the first echo, whereas for sequence 8 it is only 1/2 when $\alpha = 90^\circ$.

The T_1 -weighting, which occurs with or without a gradient, means that the echo-train does **not** decay as T_2 . The echo-magnetizations for the two sequences 7 and 8 are shown in Figure 8.

The lengths of the calculated echo-trains are different for the two sequences even though relaxation is not included: the echo-train from sequence 8 converges to zero, *whereas the quadrature sequence 7 produces a finite echo-asymptote*, approximately $\sqrt{2}$ times the initial magnetization.²⁷ An analogy may be drawn with constructive and destructive interference. The quadrature sequence is consequently the most commonly used one in STRAFI-imaging experiments.

3.7 Calibration of the Tip-Angle in STRAFI-Work

This is not trivial in the STRAFI-field since the tip-angle varies across the slice as shown by the occurrence of Primary Hahn echoes. Nevertheless one can employ a ‘nominal’ tip-angle, which is effectively the angle for the center of the slice.

In the first STRAFI pulse-calibration method, a value of 120° was taken as the angle, $\alpha_{\max}$, corresponding to maximum signal when the quadrature sequence 7 was used. This followed from calculations which used the Bloch treatment and assumed the delta-approximation.³⁵ It is interesting that Hahn gave $\alpha = 120^\circ$ as the condition for maximum amplitude of

Figure 8 Calculated echo-amplitudes as a function of echo-number for the 90° quadrature sequence 7 (circles) and the in-phase sequence 8 (triangles). Relaxation and diffusion effects are ignored. The amplitude of the first echo is the same in both cases

Figure 9 GAMMA calculated echoes from the in-phase sequence as the tip-angle is changed. The up-down pattern has three up and three down for 60° , two up and two down for 90° , and (not shown) 4 up and 4 down for 45° . Single proton; $\nu = 300$ MHz; $t_p = 10$ μ s; $\tau = 50$ μ s, $G = 50$ Tm $^{-1}$, SysLen = 5 μ m, 3000 subsystems. (Courtesy of Dr. S. A. Smith)

the echo in the $G = 0$ case, hence the result above. GAMMA-STRAFI calculations, which use the density matrix approach and in which proper summation across the slice is carried out, give $\alpha_{\max} = 140^\circ$.

A preferred method for calibration uses pulse-sequence 8. This leads to an up-down sequence of echoes: two up and two down signifies that the tip-angle is 90° ; three up and three down indicates 60° ; and so on, the general formula being $180/m$ where m is an integer.³⁶ The method is convenient since an immediate if approximate assessment of the pulse-angle is obtained for any initial angle. GAMMA-STRAFI calculations reproduce the experimental results: see Figure 9.

Alternatively one can use the shape of the first echo for calibration: GAMMA-simulations are shown in Figure 5. This method is probably the most accurate since it minimizes both relaxation and diffusion effects on the echo-intensities. The shape of the echo can be parameterized and a look-up table incorporated in the spectrometer computer to deduce the pulse-duration, δt , for say a 90° pulse, from an array of spectra as a function of δt .

3.8 Quadrupolar Nuclei: Half Integral Spin

Many quadrupolar nuclei having half-integral ($I = n/2$) spins have been studied in STRAFI-gradients. Examples include all odd values of n from 3 to 9.

It has been shown both by computation, see Figure 10, and by experiment that the echo-shape depends upon the electric quadrupolar coupling constant.³⁷ The different contributions to

Figure 10 The first three calculated echoes for sequence 7 as a function of the assumed quadrupolar coupling constant for a powder containing a spin 3/2 nucleus. (Courtesy of P. R. Bodart)

Figure 11 Responses to pulse-sequence 7 of ^{23}Na ($I = 3/2$) in powders of NaCl ($C_q = 0$) and Na_2SO_4 ($C_q = 2.6$ MHz and the asymmetry parameter = 0.6): $\nu = 32.2$ MHz; $t_p = 4.7$ μs ; $\tau = 40$ μs ; $B_1 = 50$ kHz; recycle time = 40 s; number of scans = 880; $G = 37.5$ Tm $^{-1}$

the STRAFI-signal from different transitions have also been computed. Experimental STRAFI-echoes for ^{23}Na , for which $I = 3/2$, were obtained for both solid sodium chloride and sulfate, which have χ values of 0 and 2.6 MHz, respectively,

Figure 12 As for Figure 11 except the sequence is the in-phase sequence 8, and the number of scans was 1,500

and asymmetry parameters of 0 and 0.6. Figure 11 shows the experimental echoes from the quadrature sequence 7 for each of the two solids and the calculated echo-train for NaCl, whereas Figure 12 contrasts the results for the in-phase sequence 8. In the latter case it can be noted that the large quadrupolar coupling constant for the sodium sulfate disturbs the results so that the normal use of sequence 8 for pulse-calibration is not possible. Effects of the coupling can be seen too in Figure 12 in the contrast between the echo-trains. The excellence of the calculations in matching the experimental results, for example in Figure 13, shows that such comparisons, with iteration of the value of the coupling constant in the calculations, could constitute a new method for measurement of the electric-quadrupolar coupling. This may be particularly useful for paramagnetic samples, which present little difficulty for STRAFI-measurements (see below).

3.9 Quadrupolar Nuclei: Integral Spin

Two cases of nuclides having integral spins ($I = 1$) have been reported: ^2H and ^{14}N .^{14,28} In each of these cases very long STRAFI echo-trains were obtained with thousands of echoes, even though in the nitrogen study the electric quadrupolar coupling constants varied from close to zero for ammonium nitrate to 4.9 MHz for sodium nitrite. Initial experiments on ^{14}N using an MSL 300 failed because the STRAFI-resonance frequency of about 9 MHz was too low. Success came with the use of a Bruker DMX 600 in the NHMFL in Tallahassee.¹⁴ The higher stray field gave a resonance frequency of 33.2 MHz.

Figure 13 Comparison of the experimental STRAFI-echoes for Na_2SO_4 , expanded from Figure 11, and echoes calculated using the known quadrupolar parameters

3.10 Paramagnetic Samples

So far there has been no problem in the production of STRAFI-echoes from paramagnetic samples. The first cases were proton-echoes from copper sulfate pentahydrate, diphenylpicrylhydrazyl monohydrate, tri (acetylacetonato) cobalt and vanadyl bis (acetylacetonate), each of which easily produced echoes provided short pulse-durations and echo-times in relation to T_2 were used.³⁸ The T_2 values are not greatly affected by the paramagnetism, at least at room temperature, in contrast to the much greater shortening of T_1 . Consequently the proton line-width in copper sulfate pentahydrate is governed by the nuclear dipole dipole interaction, as for diamagnetic hydrates.

Both ^{19}F and ^1H nuclides in organic ligands co-ordinated to a variety of lanthanide metals, including holmium, which has a larger paramagnetic susceptibility (10 Bohr magnetons) than the other members of the series do, also gave no problems.³⁹

More surprisingly and significantly both the paramagnetic and quadrupolar nature of vanadium ($I = 7/2$) in vanadyl bis aceto acetylacetate did not interfere with echo-formation for ^{51}V . Similarly for ^{59}Co ($I = 7/2$), STRAFI-resonances have been obtained from a variety of paramagnetic (Co II) cobalt samples, as well as diamagnetic (Co III) complexes. Generally the intensities are lower for the former presumably because of shorter T_2 values. STRAFI-methods may therefore prove to be very useful for the study of paramagnetic compounds with quadrupolar nuclides.

3.11 Enhancements: Double Resonance

In conventional imaging of liquid samples, as in spectroscopy, double resonance (DR) has been usefully employed

to enhance the signal of one nuclide by cw irradiation or pulsed-irradiation of the transitions of another. Both direct and indirect (inverse) methods have employed such as the Nuclear Overhauser Effect in $^1\text{H}\{-^{15}\text{N}\}$ experiments, or narrowing of lines broadened by a coupling to a quadrupolar nucleus as in $^1\text{H}\{-^{14}\text{N}\}$ experiments.^{40,41} 'Edited' images of only those protons attached to nitrogen are produced in each case. Concerning the imaging of solids, successful $^1\text{H}\text{-}^{31}\text{P}$ cross-polarization imaging experiments in modest gradients on chicken-bone have been reported.⁴² The DR-technique therefore holds out hope of reducing the long experiment times necessary in STRAFI- cases which are caused by the large band-widths and the single-point nature of the experiments. The band-width problem could be overcome by the use of line-narrowing techniques.

Preliminary STRAFI-DR results have been obtained in the case of solid KPF_6 . Modest ^{31}P enhancements have been reported for ^{19}F pre-saturation (26%), and cross polarization (16%).²⁹ Initial attempts at line-narrowing failed, however.

4 STRAFI-IMAGING IN 1-DIMENSION

The imaging experiment in one spatial dimension may be performed in four main ways depending on the size of the phantom. These techniques are:

- Fourier Transformation
- Frequency sweep
- Field sweep
- Sample translation

Figure 14 STRAFI-FT of the protons in the material of a container of fruit juice. The right hand signal is from a marker. (Courtesy of Dr. A. A. Samoilenko)

If the sample size is less than the excited slice-thickness then the whole of the phantom may be excited by the rf if very short pulses are used. Fourier transformation of the signal then yields the 1-D projection. This *FT-method* is useful for thin objects and has been exploited extensively for thin films, wafers and sheets. An example is shown in Figure 14. For protons a spatial resolution of about $5\text{ }\mu\text{m}$ for solids has been demonstrated for a gradient strength of 37.5 Tm^{-1} . The resolution is capable of improvement at higher values of G .

In other cases where the phantom is larger than the thickness of the excited slice, there are three basic methods for imaging: frequency-sweep, field-sweep, and translation of the sample. The problem with the *frequency-sweep method* is that large sweep-widths of the order of MHz are needed and the coil does not remain in tune unless the Q is unacceptably small. The *field-sweep method* requires a spectrometer which has the appropriate field-sweep coils, either built-in or added.⁴³ Built-in sweep-coils are not very common for superconducting solenoids. Although both of these methods have been demonstrated it is the fourth one, *sample translation*, the one originally used by Samoilenko, which has been most commonly used.

4.1 Sample Translation

This method is normally employed with the quadrature pulse-sequence with sampling of the echo-tops. The sample is then moved step-wise through the position of the sensitive plane. The step-size is of the order of the slice-thickness for the best resolution: if it is larger then the resolution is degraded. An alternative method, 'on the fly', has a continuous motion of

the sample. In this case the motion has to be slow enough not to introduce phase-shifts. There is no FT: the magnetization at each position is simply summed and recorded.

4.2 Accumulation

There is a choice between repeating the echo-trains at each position in the traverse, with a delay between each, and taking only one traverse, or, more commonly, moving the sample after the collection of a train from one slice to the next slice without a delay, and making many traverses. Since one complete traverse and return of the sample to the initial position takes a time Θ , which is of the order of one or two seconds, this second method allows Θ to be used as part of a T_1 -relaxation delay. In either case many pulses may be used in each sequence to yield long echo-trains. These are T_1 -weighted and may be summed in the method of Long Echo-Train Summation (LETS). Solids are normally endowed with large T_1 values so this method of accumulation is of considerable advantage in STRAFI-studies.

4.3 Quadrupolar Nuclides

Examples of 1-D profiles from a selection of quadrupolar nuclides are shown in Figure 15, as well as the spin-half example of ^{31}P (in red phosphorus), for which an example of a moderately long echo-train is shown since the STRAFI-decay is long. In each case the phantom was divided into two volumes with a spacer of thickness 0.65 mm. The spacer is clearly resolved. In some cases it can be seen that profiles for

Figure 15 1-D profiles for ^{31}P and a variety of quadrupolar nuclides taken using the translation method (see text). The gap is 0.65 mm in each case. (Courtesy of Dr. A. A. Samoilenko)

different nuclides overlap, because of the closeness of their γ -values (see equation (2)).

4.4 Multinuclear Profiles

Separate ^{11}B and ^1H profiles of a phantom containing sodium borohydride, sodium borofluoride, and sodium borate decahydrate have been reported,⁴⁴ and more recently ^{31}P and ^1H profiles of the same section of dried chicken bone have been obtained.

There are several examples of *simultaneous* procurement of profiles of pairs of nuclides which have γ -values which are close to each other, in addition to those noted above for quadrupolar nucleides.

The examples are mainly for the proton-fluorine pair, including one involving dental cement.⁴⁵ The original study¹³ included three experiments: one with solid discs of the polymers PMMA and PTFE (spatial separation of H and F); the second had a disc of nylon being ingressed by 2,2,2 trifluoroethanol (H in the solid, and both H and F in the same liquid); and the third had a fluorine-free polymer (used as a cement for bone prostheses), being ingressed by a perfluorinated solvent, hexafluorobenzene.¹³ In each case both the ^1H and ^{19}F images are obtained in one traverse with the Bruker probe. The appearance of the image depends on whether the F- or the H-containing parts of the phantom enter the fringe-field first: the maximum separation of the ^1H and ^{19}F images occurs when it is the proton: see Figure 16.

The only other pair noted so far is ^7Li and ^{31}P . The displaced profiles were obtained from a number of ceramics and glasses on the high field Tallahassee system at 202 MHz, at which frequency the relative γ -displacement is 6.45 mm.

Figure 16 1D-profiles for ^1H - in a PMMA disc of height 2 mm and ^{19}F in a PTFE disc 3 mm high showing the γ -shift (see text). The discs are in contact and the separation of the sensitive planes is about 4.9 mm. The top scan (a) was taken with the fluorine disc entering the STRAFI-region first. The bottom scan (b) was after a 180° rotation of the phantom. $\nu = 123.4\text{ MHz}$ and $G = 37.5\text{ Tm}^{-1}$

5 STRAFI-STUDIES IN 2- AND 3-DIMENSIONS

Most STRAFI-studies employing sample movement have been accomplished in one dimension and have involved a simple translation of the phantom. Since in this mode the STRAFI-technique is essentially a single point method and because of the large band-width for solids, it is time-consuming. In general it has been more advantageous to design the experiment to yield the desired information from one dimension than to use 2- or 3D-STRAFI-imaging. Of course this is not always possible, for example for bones and many other materials.

The translation method in which the sample is moved along the z-axis of the solenoid along which G varies may be extended to a second spatial dimension by a rotation around an axis perpendicular to z, say around the x-axis, and to a third dimension by a second orthogonal rotation around the y-axis. There is a 3D proton STRAFI-study of an extracted first mandibular tooth.⁴⁶ For very small samples for which the 1-D FT method may be applied, i.e., for which the excited slice is potentially wider than the sample in any orientation, a second dimension may be obtained by one rotation, as has been achieved by Newling. It is possible to add a third dimension by a second orthogonal rotation as for the extension of the translation method.

6 APPLICATIONS

Most reported STRAFI-applications have been confined to proton work in one dimension, and most of these have employed the method of sample translation, although an increasing number employ the FT-method. Many of the applications only mentioned briefly below have been comprehensively reviewed by Newling and McDonald.⁹

A seminal STRAFI-study was the examination of acetone ingressing into poly(vinyl chloride), PVC.⁴⁷ For the first time protons in all three environments, polymer, softening polymer and ingressing liquid, were imaged at high spatial resolution, about $80\text{ }\mu\text{m}$. Results from relaxation-weighting and per-deuterated acetone experiments allowed discrimination of the overlapping contributions of liquid and softening polymer. The mechanism of ingression and the rates of softening of the polymer were reported. Great pains were taken by the Surrey group to yield phantoms suitable for 1-D studies. A number of PVC samples were placed in acetone atmospheres at different partial pressures of acetone and different temperatures. In each case the sample was then frozen to stop the process and the frozen solid was machined down to 10 mm cubes to yield a phantom which had only one surface exposed to the acetone. In other words the ingression was not followed on one sample, as in subsequent work. Each profile took about 30 minutes to one hour to acquire.

The STRAFI-method is very useful for such temporal studies because of its non-invasive nature. Subsequently there have been many similar studies on organic polymers such as with mixed solvents, for example methanol and acetone with poly(methylmethacrylate).⁴⁸ Other polymers investigated by the STRAFI-method include poly(ester) and epoxide resins,⁴⁹ extruded poly(propylene),⁵⁰ microbial poly(saccharides),⁵¹ and polystyrene.⁵² A 3-D study was used on poly(ethylene glycol) and poly(vinyl alcohol) binders.⁵³ Other classes of mainly

organic materials are glues and coatings, latex paint, creaming of emulsion layers, adhesive tapes, and photographic films.

The class of porous inorganic minerals and materials has also been studied quite extensively. These are heterogeneous and suffer in normal imaging studies from short T_2 -values, and from the effects of magnetic susceptibility variations, neither of which affect STRAFI-imaging to the same extent as conventional studies. All categories of protons may be detected. In the case of water detection of all types and conditions is possible: from bound or co-ordinated water, ice, water in pores and capillaries, to more mobile water in

Figure 17 STRAFI-profiles for water-protons in a soil sample being drained to various matric potentials. Bulk water is shown at the left at a and is given unit intensity. The water and the wet soil are separated by a porous disc at b. The matric potentials are given in hPa. Each image is from 146 slices $360\mu\text{m}$ apart and each point is the sum of the total intensity of an echo-train 32 echoes long. $\nu = 111\text{ MHz}$ and $G = 12.0\text{ Tm}^{-1}$. (Courtesy of Dr. A. R. Preston)

Figure 18 Spatial dependence of the amplitudes of two exponential decay-terms needed to fit the water-proton peak-amplitudes from a series of positions along a bi-wedge (inset). The cylindrical bi-wedge has a diameter of 31 mm and length of 24 mm . Its two parts are separated by an acetate sheet. Each part was cut from a Coralith ceramic having pores characterized by a single-size pore-diameter: $1\mu\text{m}$ and $20\mu\text{m}$ respectively. The relaxation time of the pore-water depends on the pore-size. $\nu = 111\text{ MHz}$ and $G = 12.0\text{ Tm}^{-1}$. (Courtesy of Dr. A. R. Preston)

Figure 19 Spatially resolved echo-trains for protons in a section of dry chicken bone without marrow. Results were from the Surrey STRAFI-system. $\nu = 236.6\text{ MHz}$; $G = 58.5\text{ Tm}^{-1}$; $t_p = 8\mu\text{s}$; $\tau = 60\mu\text{s}$; number of echoes, 128 in each train, recycle time 0.1 s . Signal at the right is from the glue holding the glass container. (Courtesy of Dr. J. Godward and Dr. D. G. Gillies)

Figure 20 Experimental and calculated points for a 1-D profile of an electrical insulating disc (outer and inner diameters of 6.4 and 3.0 mm respectively, height 15 mm) made of aluminium oxide. The gradient was 75.7 Tm^{-1} that of a Magnex magnet of bore 31.6 mm with center field of 19.6 T . The STRAFI-nucleus was ^{27}Al ; $\nu = 124.3\text{ MHz}$; $t_p = 4\mu\text{s}$; $\tau = 103\mu\text{s}$; recycle delay of 0.2 s ; 100 scans for each position. Only two pulses were used each time giving a single echo. (Courtesy of Dr. V. Soghomonian and A. R. Samoilenko)

gels or in free water. Rocks, soils, cements and other building materials, such as tiles, may be studied advantageously by the STRAFI-method, which can yield not only images but spatial variation of relaxation parameters and diffusion constants.

There is only a small number of STRAFI studies in 3D. Two early studies were of water: firstly in a narrow tube surrounded by nickel sulphate crystals, which severely distorted a conventional image taken in the center field because of susceptibility effects but not the STRAFI-results;² and then a study of water and plant-material in soil.³ Other 3D-work, in addition to the investigation of a mandibular tooth⁴⁶ includes Zick's imaging of a poly-carbonate plug, and Wang's study of unsintered green ceramics.⁹

Figure 21 The STRAFI-system at Queen Mary, University of London. The stepper motor is mounted on a table bolted to the floor. The sliding carriage is shown in close-up together with the coil-system (5 cm bore), a copper shielding box, and a phantom surmounted by a rubber bung contained in a glass cylinder. (Courtesy of Dr. P. Kinchesh)

Soil-water, including the pore-size distribution, is now being studied as a function of matric potential (hydrostatic pressure) see Figure 17, a possibility which may be extended to other materials.⁵⁴ The advantage of STRAFI-work is that it can reach water even in the smallest pores and also bound water. A problem even with the STRAFI-technique in investigations of ice, whether in bulk or in pores, is the complication of the very short T_2 which is of the order of $5\mu\text{s}$ for ^1H : very short pulse-durations and echo-times are required. Nevertheless both heavy water and heavy ice,²⁸ and water and ice, have been studied by Nunes et al. An illustrative example of work on water in porous ceramics is shown in Figure 18.⁵⁵

Work with medical potential, in addition to that on dental materials, is STRAFI-work on bones: one may use either ^{31}P or ^1H . Proton-work on bone is illustrated in Figure 19, which shows the STRAFI-profile, in the form of spatially separated echo-trains, of a section of dry chicken-bone without the marrow.

Work on other nuclei may be contemplated, such as ^{27}Al in cements provided ^{23}Na does not interfere. Lastly we conclude with a high field example of STRAFI-work on ^{27}Al in an electrical insulating disc of aluminium oxide as shown in Figure 20. Other exploratory work on this 19.6 T system at the NHMFL was with the nuclides ^1H , ^2H , ^7Li , ^{23}Na and ^{31}P .

7 PROSPECTS

STRAFI-work has been curiously slow to spread, despite its strengths as demonstrated for example by the applications published by the Surrey and Lisbon groups.⁹ Nevertheless its worth is being increasingly appreciated particularly by the materials community. One disadvantage is that currently there is no commercial STRAFI-package available, indeed only Bruker, where the technique was largely developed, has ever offered a commercial STRAFI-system. The STRAFI-additions to instruments at Surrey, Tallahassee and Queen Mary, have each been made in-house. The STRAFI-apparatus, developed at Queen Mary around a Varian/Sisco system with an Oxford magnet, to a STRAFI-design by Andre Samoilenko, is shown in Figure 21.

Acknowledgements

I am grateful particularly to Andrei Samoilenko, the father of the technique, for our stimulating periods of work together, to Teresa Nunes in Lisbon and Peter McDonald in Surrey for making me so welcome in their respective laboratories, and indeed to all my STRAFI-collaborators from the first, Paul Kinches and Klaus Zick, to Alex Bain, Scott Smith and Philippe Bodart for computations, and to the latest, Alasdair Preston, for enlightenment. I am greatly obliged to collaborators for permission to include work which is not in the open literature or is not yet published. Thanks too, to Dr. Nathalie Mahieu and Alasdair Preston for help with the figures.

Biographical Sketch

Edward Randall, b 1933 in Liverpool and educated at Magdalen College Oxford. He began research in magnetic resonance as a post-doctoral fellow at Harvard (1959–61) with some of the first double resonance studies, which he continued at Queen Mary College. There he ran a National NMR Service on the first commercial pulse-FT spectrometer in the UK beginning in 1970. His own group specialized in ¹⁵N studies including the first studies of peptides, and ¹³C and ¹⁷O work on organometallics. He began imaging in 1991 using both direct and new indirect spin-echo techniques for both ¹⁴N and ¹⁵N in liquids. He then turned to the difficult task of imaging solids and was one of the first to use and adopt the STRAFI-technique in 1992. Working in Lisbon, Surrey, and more recently in Tallahassee, he has published more than 30 STRAFI-papers in which he showed that any nucleus in virtually any solid can be imaged.

Wavelet Encoding of MRI Images

Lawrence P. Panych and Ferenc A. Jolesz

Brigham and Women's Hospital and Harvard Medical School,
Boston, MA, USA

1 INTRODUCTION

In Fourier transform MRI, the raw image data can be expressed mathematically as samples of the Fourier transform of a spatially dependent density function that is proportional to the magnitude distribution of the transverse magnetization. Thus, the raw Fourier image data represent a spatial frequency decomposition of the density function. In wavelet encoding of MRI images, one attempts to image in such a way that the raw image data can be expressed as samples of the wavelet transform of the density function along at least one spatial dimension. The raw wavelet image data have some characteristics of a spatial frequency decomposition, but they also retain features of the spatial domain representation.

More formally, let $s(x)$ represent the density function. The Fourier transform of $s(x)$ is a function $S(k)$ of the spatial frequency parameter k , and $|S(k)|^2$ gives a measure of the 'energy' content in $s(x)$ at the spatial frequency k (in cm^{-1}). The wavelet transform of $s(x)$ is a function $S_w(v, u)$ of two parameters: a 'scale' (spatial frequency band) parameter v and a location parameter u . $|S_w(v, u)|^2$ gives a measure of the 'energy' content in $s(x)$ at the scale v (in cm^{-1}) in the vicinity of the location u (in cm).

In Fourier transform MRI, the raw Fourier domain data are produced by manipulation of the phase angle of the transverse magnetization. In wavelet MRI, on the other hand, it is the angle of the magnetization vector between the longitudinal axis and the transverse plane that is manipulated. In other words, the amount of the magnetization tilted into the transverse plane is modulated according to wavelet-shaped excitation profiles. This is done by modifying the rf excitation pulses on each encoding step.

In this article, wavelet encoding in one of the dimensions of a two-dimensional imaging method is described. The second dimension is Fourier-encoded because, during the data acquisition period of an imaging sequence, it is not possible to manipulate the flip angle of the spins, nor is it possible (with linear gradients) to wavelet-encode the phase angle of the transverse magnetization. Thus, the so-called frequency-encoding dimension must be Fourier-encoded. Figure 1 shows a modified line scanning sequence that has been used^{1,2} to encode two-dimensional images with wavelet encoding along one of the dimensions (y). The wavelet encoding method using this sequence applies ideas first proposed by Healy and Weaver.^{3,4} Wavelet encoding has also been implemented in the slice-select direction using a multislice gradient echo sequence with wavelet-shaped slice profiles.⁵

2 WAVELET TRANSFORM THEORY

2.1 Continuous and Discrete Wavelet Transform

A wavelet transform⁶ $F_\Psi(v, u)$ of the real-valued finite-energy function $f(x)$ is defined by

$$F_\Psi(v, u) = |v|^{-1/2} \int f(x) \Psi\left(\frac{x-u}{v}\right) dx \quad v \neq 0 \quad (1)$$

$\Psi(x)$ is the real-valued 'basic' wavelet function, and is a window on $f(x)$ that is both scaled (v) and translated (u). For practical applications such as imaging, it is important to know if a function can be recovered from a discrete and finite sampling of its wavelet transform space. When the sampling is exponential as expressed by

$$v = 2^j, \quad u = 2^j n, \quad \text{where } j \text{ and } n \text{ are integers} \quad (2)$$

a family of 'dyadic' wavelets $\{\Psi_{j,n}(x)\}$ is produced as defined by

$$\Psi_{j,n}(x) \equiv 2^{-j/2} \Psi(2^{-j}x - n) \quad (3)$$

$\Psi(x)$ have been found such that the set of dyadic wavelets defined by equation (3) is orthonormal, and arbitrary functions can be represented by a series with the same number of terms used in a Fourier expansion. In fact, for functions with distinct edges (as are typical in MRI), even fewer terms are generally needed in the wavelet representation. Figure 2 demonstrates how a set of dyadic wavelets is constructed by scaling of the basic wavelet and then translating (in steps of $2^j \Delta x$) each of the scaled wavelets.

2.2 Wavelet Multiresolution Analysis

Multiresolution analysis⁷ provides an elegant interpretation of the dyadic wavelet expansions. The central idea of multiresolution analysis is that the space of finite-energy functions can be decomposed into a hierarchy of subspaces $\{\mathbf{V}^{[j]}\}$ where $\mathbf{V}^{[j]}$ is the space of all approximations of the finite-energy functions at the resolution $2^j \Delta x$ (j integer). Resolution is defined such that, at the resolution $2^j \Delta x$, a function $f(x)$ is approximated by evenly spaced samples of width $2^j \Delta x$. Note that, by the convention adopted here, a higher index j corresponds to a poorer (coarser) resolution.

Figure 1 Pulse sequence for wavelet encoding in the y dimension

Figure 2 A wavelet basis is constructed by scaling the basic wavelet. The top row of plots shows Battle-Lemarie wavelets at three dyadic scales. At each scale, the wavelets are translated in increments of $2^j \Delta x$ as shown in the bottom row of plots for the scale j . In this figure, only every 16th translate is plotted, and the positions of all other translates are shown with tick marks

Approximation spaces are defined such that $\mathbf{V}^{[j+1]}$ is completely contained within the finer resolution subspace $\mathbf{V}^{[j]}$. The extra detail found in $\mathbf{V}^{[j]}$ that is not also found in $\mathbf{V}^{[j+1]}$ is included within the detail space $\mathbf{W}^{[j+1]}$ as formalized by

$$\mathbf{V}^{[j]} = \mathbf{W}^{[j+1]} \cup \mathbf{V}^{[j+1]} \quad (4)$$

Each of the approximation subspaces $\mathbf{V}^{[j]}$ is spanned by a family of scaling functions, $\{\Phi_{j,n}(x)\}$, as defined by

$$\Phi_{j,n}(x) = 2^{-j/2} \Phi(2^{-j}x - n\Delta x), \quad \text{where } j \text{ and } n \text{ are integers} \quad (5)$$

and where Δx is the width of the basic scaling function⁶ $\Phi(x)$. Each detail space $\mathbf{W}^{[j]}$ is spanned by a family of wavelets $\{\Psi_{j,n}(x)\}$ defined by

$$\Psi_{j,n}(x) = 2^{-j/2} \Psi(2^{-j}x - n\Delta x), \quad \text{where } j \text{ and } n \text{ are integers} \quad (6)$$

Figure 3 shows examples of basic scaling functions and wavelets used to build orthonormal bases.

A wavelet transform decomposes a function into an expansion in terms of functions built from the scaling functions and wavelets as follows. Assume that the function of interest is contained within the approximation space $\mathbf{V}^{[0]}$. Any function in $\mathbf{V}^{[0]}$ can be expressed as a weighted sum of the scaling functions $\{\Phi_{0,n}\}$ that span $\mathbf{V}^{[0]}$. However, since $\mathbf{V}^{[0]} = \mathbf{W}^{[1]} \cup \mathbf{V}^{[1]}$, it can also be expressed as a weighted sum of the scaling functions $\{\Phi_{1,n}\}$ and the wavelets $\{\Psi_{1,n}\}$ that span the subspaces. Further, since $\mathbf{V}^{[1]} = \mathbf{W}^{[2]} \cup \mathbf{V}^{[2]}$, any function in $\mathbf{V}^{[0]}$ can also be expressed as a weighted sum of the scaling functions $\{\Phi_{2,n}\}$ and the wavelets $\{\Psi_{2,n}\}$ and $\{\Psi_{1,n}\}$. The wavelet decomposition can be continued to an arbitrary scale J , so that the approximation of $f(x)$ in $\mathbf{V}^{[0]}$ is expressed as a weighted sum of wavelets $\{\Psi_{1,n}\}$, $\{\Psi_{2,n}\}$, ..., $\{\Psi_{J,n}\}$ and the scaling functions $\{\Phi_{J,n}\}$.

On a finite interval of length $N\Delta x$, J cannot be greater than $\log_2 N$. Each set of wavelets $\{\Psi_{j,n}\}$ or scaling functions $\{\Phi_{j,n}\}$ contains $N/2^j$ functions, since the translation step size for each scale j is $2^j \Delta x$. Problems at the edges of finite intervals are avoided if it is assumed that the basis functions wrap around at the edges.

The approximation of $f(x)$ in $\mathbf{V}^{[0]}$ on the finite interval of length $N\Delta x$ can be expressed by the wavelet series expansion

$$f^{[0]}(x) = \sum_{j=1}^J \sum_{k=0}^{N/2^j-1} D_{j,k} \Psi_{j,k}(x) + \sum_{l=0}^{N/2^J-1} A_{J,l} \Phi_{J,l}(x) \quad (7)$$

where the total number of terms in the expansion is N and the weights $A_{j,n}$ and $D_{j,n}$ are defined by

$$A_{j,n} = \int f(x) \Phi_{j,n}(x) dx, \quad D_{j,n} = \int f(x) \Psi_{j,n}(x) dx \quad (8)$$

2.3 Multiresolution Wavelet Reconstruction

The sets $\{D_{1,k}\}, \dots, \{D_{J,k}\}$ and $\{A_{J,l}\}$ in equation (7) are the coefficients of a discrete wavelet transform of $f(x)$. Reconstruction begins with the data sequences $\{A_{J,l}\}$ and $\{D_{J,l}\}$. The multiresolution interpretation says that the sequence $\{A_{J,l}\}$ represents the coarsest approximation of $f(x)$, and $\{D_{J,l}\}$ represents the detail between the coarsest approximation and an approximation one level finer.

To move to a finer level of approximation, zeros are inserted between each value in the two sequences. The zero-padded sequences are then individually convolved with the impulse response of a low- and a high-pass filter,⁷ and the convolution results are added. In this way, the sequence $\{A_{J-1,k}\}$ is produced. It has twice as many values as $\{A_{J,l}\}$, and represents a discrete approximation of $f(x)$ at the second coarsest resolution. To move to another scale, $\{A_{J-1,k}\}$ and $\{D_{J-1,k}\}$ are padded with zeros and convolved with the same low- and high-pass filters, and $\{A_{J-2,k}\}$ is produced. The process is continued until all of the detail sequences are merged and the N -element sequence $\{A_{0,k}\}$ is the final result. $\{A_{0,k}\}$ represents a discrete approximation of $f(x)$ at the resolution Δx .

Figure 3 Basic scaling functions and wavelets for the Haar basis (Φ_H, Ψ_H), a Daubechies basis (Φ_D, Ψ_D), and the Battle-Lemarie basis (Φ_L, Ψ_L)

3 MR ENCODING BY SPATIALLY SELECTIVE EXCITATION

Assume that the modified line scan sequence shown in Figure 1 is used and, on each of N excitations, a set of profiles, $\{\phi_{0,n}(y)\}$, defined by

$$\phi_{0,n}(y) = \phi(y - n\Delta y), \quad n = 0, 1, \dots, N-1 \quad (9)$$

is excited, where $\phi(y)$ is centered at $y = 0$, has a width of Δy , and is mostly positive. The general form of the echo data from the n th excitation, $S_n(k_x)$, is expressed by

$$S_n(k_x) = \iint s(x, y) \phi_{0,n}(y) e^{ik_x x} dx dy \quad (10)$$

where $s(x, y)$ is the magnetization density function introduced in Section 1.

Assume that N (k -space) samples are taken from each echo. After performing an inverse fast Fourier transform (FFT) on each of the N sets of echo data with respect to k_x , the partially transformed data set $\{s_{m,n}\}$ can be expressed by

$$s_{m,n} = \int \int s(x, y) \text{sinc}\left[\frac{\pi}{\Delta x}(x - m\Delta x)\right] \phi_{0,n}(y) dx dy \quad (11)$$

$$m, n = 0, 1, \dots, N-1$$

where the sinc function represents the point spreading due to finite k -space sampling. Clearly, $\{s_{m,n}\}$ is a discrete approximation of $s(x, y)$, since $\phi_{0,n}(y)$ in equation (11) also acts like a point-spread function. In fact, if $\phi(y)$ is a sinc function and $\Delta y = \Delta x$ then the N^2 values of $\{s_{m,n}\}$ should be identical to an image obtained using phase encoding.

Now, suppose that $\phi(y)$ is a scaling function $\Phi(y)$ such as one of those shown in Figure 3. In this case, $\{s_{m,n}\}$ is also a discrete approximation of $s(x, y)$, but with a different point-spread function in the y direction. If equation (11) is rewritten as

$$s_{m,n} = \int \bar{s}(m\Delta x, y) \Phi_{0,n}(y) dy \quad (12a)$$

where

$$\bar{s}(m\Delta x, y) \equiv \int s(x, y) \text{sinc}\left[\frac{\pi}{\Delta x}(x - m\Delta x)\right] dx \quad (12b)$$

and compared with the definition of $A_{j,n}$ in equation (8), it is clear that $s_{m,n}$ has the same form as $A_{0,n}$. For any x -location index m , $\{s_{m,0}, s_{m,1}, \dots, s_{m,N-1}\}$ represents a set of coefficients $\{A_{0,n}\}$, and can be interpreted as a discrete approximation of $\bar{s}(m\Delta x, y)$.

At low flip angles, a scaling-function-shaped profile $\Phi(y)$ can be excited using an rf pulse whose shape is given by the Fourier transform of $\Phi(y)$. In order to translate the profiles across the field of view in steps of Δy , the rf offset frequency must be changed, on each excitation, in steps of $\Delta\omega = \gamma G_y \Delta y$, where G_y is the strength of the y gradient during the rf excitation. If $T_{3\text{dB}}$ is the half-power (3 dB) duration of the rf pulse [see RFS(0) in Figure 4] then the width of the excitation profile is $(\gamma G_y T_{3\text{dB}})^{-1}$, since the rf pulse excites a region proportional to its bandwidth. The translation step size Δy must be equal to the width of the excitation profile $\Phi(y)$; therefore, $\Delta\omega = 1/T_{3\text{dB}}$.

For a fixed gradient strength and fixed total rf pulse duration T_{rf} , the achievable resolution Δy is strongly dependent on the type of scaling function. The best resolution is achieved when the ratio $r = T_{3\text{dB}}/T_{\text{rf}}$ approaches 1. To produce the sharp edges of the Haar scaling function, many sidelobes of a sinc-shaped rf pulse must be included, and r will be much less than 1. On the other hand, r for the Battle-Lemarie scaling function is $\frac{2}{3}$, and the resolution will be closer to the maximum, which is obtained when the rf pulse is box-shaped.

4 AN IMPLEMENTATION OF WAVELET-ENCODED MRI

4.1 Excitation Profiles and rf Pulses

From the multiresolution interpretation of the wavelet transform, we know that any function that can be represented by a weighted sum of scaling functions $\{\Phi_{0,n}(y)\}$ can also be represented by a weighted sum of the set of wavelets at the J scales and the set of scaling functions at scale J . For wavelet encoding, then, the pulse sequence shown in Figure 1 is used to excite specially shaped excitation profiles on each of N separate excitations in the same manner as in Section 3. In the wavelet case, however, the excitation profiles will be the $N/2$ wavelets $\{\Psi_{1,n}(y)\}$, the $N/4$ wavelets $\{\Psi_{2,n}(y)\}, \dots$, the $N/2^J$ wavelet(s) $\{\Psi_{J,n}(y)\}$, and the $N/2^J$ scaling function(s) $\{\Phi_{J,n}(y)\}$.

To generate wavelets at different scales, there are two choices:

1. use a constant gradient strength while varying the duration of the rf pulse at each scale; or
2. use an rf pulse of constant duration while varying the gradient strength at each scale.

Figure 4 shows a set of rf pulses to be used for wavelet encoding ($J = 3$) in the Battle-Lemarie basis using the constant gradient method. Note that RFS(0) is not needed for wavelet encoding. The rf pulses are shown as magnitude-normalized; however, if it is desired to maintain a constant flip angle at all scales, rf pulse amplitudes will be scale-dependent. Figure 4 also shows the (magnitude-normalized) profiles excited by each pulse. In the variable-gradient method, independent of the number of scales, only two different rf waveforms are needed (one for scaling functions and one for wavelets). If this method is used, however, gradient-strength-dependent imperfections such as eddy currents may result in image artifact.

4.2 Image Reconstruction

Assume that N wavelet-shaped profiles, as described in Section 4.1, are excited using the pulse sequence shown in Figure 1, and that N samples are collected on each echo. An inverse FFT is performed on each of the N sets of echo data, and the partially transformed data can be expressed as in equations (11) and (12a,b), with the exception that wavelet functions at the J scales and scaling function(s) at scale J replace the set of functions $\{\phi_{0,n}\}$ or $\{\Phi_{0,n}\}$. The expression for the partially transformed data has the same form as the definitions of $A_{j,n}$ and $D_{j,n}$ in equation (8). Thus, for any x -location index m , the N transformed data values represent the coefficients

Figure 4 The top four pairs of plots are (amplitude-normalized) rf pulses and excitation profiles for a three-level wavelet encoding. See Section 3 for a discussion of RFS(0) and $\Phi_0(y)$. All profiles are computed assuming a gradient strength of 10 mT m^{-1}

$\{D_{1,k}\}, \dots, \{D_{J,k}\}$ and $\{A_{J,k}\}$, which can be interpreted as a discrete wavelet transform of $\bar{s}(m \Delta x, y)$.

The reconstruction procedure outlined in Section 2.3 is used to transform the wavelet coefficient data for each x -location index m into a set $\{A_{0,n}\}$, which represents a discrete approximation of $\bar{s}(m \Delta x, y)$ of resolution Δy . In theory, then, the result obtained after complete reconstruction should be the same as if the pulse RFS(0) shown in Figure 4 had been used to excite the scaling function profiles $\{\Phi_{0,n}\}$.

5 SIGNAL-TO-NOISE RATIOS

It has previously been noted^{4,8} that wavelet encoded images suffer a disadvantage in terms of signal-to-noise ratio (ratio of signal energy to noise energy) when compared with standard phase-encoded images. The intuitive explanation for this is that all spins participate in each phase encode, whereas only a small portion of the spins are, on average, involved during each wavelet encode. When wavelet encoding, on $N/2$ of the encod-

ing steps $2/N$ of the spins are excited, on $N/4$ of the steps $4/N$ are excited, on $N/8$ of the steps $8/N$ are excited, and so on. It can be shown^{9,10} that the signal-to-noise ratio for wavelet encoding is only $3/N$ of that obtained when phase encoding. Of course, since wavelet encoding generally involves only a small portion of the spins, there is a possibility that many wavelet encodes can be interleaved in a TR period, and the loss in signal-to-noise ratio may be compensated by an increase in the information rate.

If wavelet packets⁶ are used instead of standard wavelets then the signal-to-noise ratio in the wavelet case can be made to approach the signal-to-noise ratio of Fourier imaging.^{8,9} Wavelet packets are built from linear combinations of the standard wavelets, and can be designed to involve much larger portions of the field-of-view than the standard wavelets. When wavelet packet functions are used for encoding, more spins on average will be involved on each encoding step, and the signal-to-noise ratio increases accordingly. Of course, since the wavelet packet functions cover larger portions of the field-of-view, spatial selectivity is traded for the increase in signal-to-noise ratio.

6 LIMITATIONS AND APPLICATIONS

Because wavelet encoding is implemented by exciting wavelet-shaped profiles, the resolution when encoding along more than one dimension is limited by the ability to excite multidimensional profiles of sufficient spatial selectivity. A new digital encoding methodology,¹¹ however, exploits a more general approach to encoding with selective excitation¹² and thereby offers greater flexibility for multidimensional wavelet encoding. The digital approach is to excite linear combinations of basic volumes, such as slices or strips, with the combinations being defined by an encoding matrix. The actual spatial profiles in digital wavelet encoding need not have true wavelet shapes, thereby giving greater flexibility in choosing the wavelet-encoding matrix.

A further limitation of wavelet encoding is that some standard fast imaging approaches may not be fully compatible. Echo-planar or fast spin-echo methods can be used to encode the third (normally slice-select) dimension. There are, however, no reports of implementations of fast single-slice two-dimensional wavelet methods. Wavelet-encoded, low flip-angle gradient-echo imaging could be used for fast two-dimensional imaging, however, only if combined with saturation techniques for slice selection in the third dimension.

The most promising application that we see for wavelet encoding of MRI images is in the development of adaptive imaging methods.¹⁰ An imaging method is adaptive if the image acquisition strategy is modified according to that which is learned about the image during data acquisition. Adaptive methods can be very effective in reducing redundancy in data acquisition and increasing response time in dynamic imaging applications. As an example of a dynamically adaptive imaging strategy based on wavelet encoding,¹⁰ data are acquired beginning with the coarsest resolution. Acquired data values are then examined to determine if a change has occurred since the last time the same coefficients were encoded. Only if change occurs at the coarser resolution are the finer detail coefficients then acquired in a region. Since the number of wavelet encodes grows (by a factor of 2) at each level of detail, this strategy leads to a very significant reduction in the number of encodes necessary to update an image when spatially localized change occurs. This type of multiresolution strategy has been applied in functional MRI in order to target regions of neuronal activation.¹⁴

Wavelet-based adaptive methods exploit the ability, when wavelet encoding, to produce images with spatially variable resolution. This ability is useful in any application, adaptive or not, where it is desired to resolve highly only a small region of interest leaving the rest of the field of view less resolved. The ability to resolve images selectively in this way, which derives from the nature of the wavelet transform as a spatially selective multiscale decomposition, is a feature that is unavailable with standard Fourier encoding.

Biographical Sketches

Lawrence P. Panych b 1950. B.Eng., 1979, McGill University; M.S., 1983, University of British Columbia; Ph.D., 1993, Massachusetts Institute of Technology 1993. Currently Assistant Professor of Radiology at Harvard Medical School and Brigham and Women's Hospital. Approx. 30 publications. Research specialties: dynamic MRI and novel encoding techniques.

Ferenc A. Jolesz b 1946. M.D., 1971, Semmelweis Medical School, Budapest; M.S., 1975, Kando College of Electrical Engineering, Budapest. Research fellowships in neurology at Massachusetts General Hospital and in physiology at Harvard Medical School. Currently B. Leonard Holman and the Image-Guided Therapy Program Professor of Radiology at Harvard Medical School and Director of the Division of MRI at Brigham and Women's Hospital, Boston. Approx. 170 publications. Research specialties: interventional MRI, image processing, demyelination, multiple sclerosis and Alzheimer's disease.

Whole Body Magnetic Resonance Artifacts

R. Mark Henkelman

Sunnybrook Health Science Center and University of Toronto,
Toronto, ON, Canada

1 INTRODUCTION

One would hope that an NMR image would show an exact one-to-one correspondence to the object being imaged. This, however, is not the case. There are many 'structures' that are observed in MR images for which there is no corresponding structure in the actual object. Because these unreal 'structures' are the product of human workmanship, they are called artifacts. Artifacts often arise from imperfections in the practical implementation of ideal imaging concepts. In this case, an understanding of the artifacts and their causes can often lead to improved imaging technique. Sometimes, artifacts are intrinsic to even an ideal imaging system, and are thus not correctable. In either case, an ability to recognize some of the wide variety of artifacts that occur in MR images protects against misinterpretation of their appearances as real structures. This is particularly important in clinical MR imaging, where artifacts have sometimes been interpreted as anatomical or pathological structures, leading to unwarranted therapeutic procedures.

Since artifacts are usually first encountered in the visual image, they are described in this article in terms of how they appear. In each case, the causes of the artifacts are identified with appropriate references to other articles of this volume where the underlying science of the data acquisition and image formation are more fully described. Some prominent artifacts are subjects in their own right, and are not discussed in any detail in this article (see *Motion Artifacts: Mechanism and Control*; *Susceptibility Effects in Whole Body Experiments*; *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control*; *Tissue Water and Lipids: Chemical Shift Imaging and Other Methods*; *Chemical Shift Imaging*; *Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas*; *Surface and Other Local Coils for In Vivo Studies*, and *Selective Excitation Methods: Artifacts*).

This overview of artifacts in whole body MRI is not exhaustive, since new artifacts are being identified whenever new pulse sequences and new applications are developed. However, this article introduces most of the classes of artifacts that are seen, and provides enough kinds of causes so that as new ones are identified, they can be readily understood. More detailed reviews of MRI artifacts have been published previously.¹⁻³

2 IMAGE WRAP-AROUND

Figure 1 shows an image with wrap-around artifact. This is due to aliasing, in which precessional frequencies beyond the

Nyquist sampling frequency appear as lower frequencies. (see *Image Formation Methods*, and *Spin Warp Data Acquisition*). Aliasing in the frequency-encode direction can be eliminated by over-sampling at a higher Nyquist frequency and digitally filtering the data as they are acquired (see *Whole Body Magnetic Resonance Spectrometers: All-Digital Transmit/Receive Systems*). Over-sampling in the phase-encode direction requires extra data acquisition time, which often is not available. Selective saturation of spins that lie beyond the image boundary can be used to suppress aliased signal (see *Selective Excitation Methods: Artifacts* and *Selective Excitation in MRI and MR Spectroscopy*). Aliasing can also occur in the slice selection direction when slices are phase encoded in three-dimensional acquisitions.

Images can also wrap over on themselves when attempts are made to image beyond the linear range of the gradient (see *Gradient Coil Systems*). It is, therefore, important in whole body imaging to ensure that parts of the body that extend beyond the useful gradient are not excited by the rf system.

3 EDGE RINGING

Edge ringing appears as a series of ripples propagating away from any sharp discontinuity in signal intensity, as shown in Figure 2. Edge ringing is a truncation artifact due to inadequate sampling of the high frequencies of k -space (see *Image Formation Methods*). It can be eliminated by sampling further in k -space with an associated increase in both image acquisition time and noise, or by low-pass filtering the acquired k -space data with an associated loss of image resolution. Alternatively, some postprocessing methods using predictive models of the missing data have been attempted with modest success.^{4,5}

Figure 1 The top of the scalp extends beyond the upper boundary of the image frame. The image of this scalp is wrapped-around, and intrudes into the bottom of the image and overlaps the neck

Figure 2 The left frame shows part of an axial brain image taken with 128 samples. The pattern of bright and dark rings propagating into the brain are edge ringing artifacts. On the right is the same image taken with 256 samples and then high-frequency-sampled to remove edge ringing. (Reproduced by permission of Dr. William Matthew Kelly, Department of Radiology, David Grant USAF Medical Center, CA)

Edge ringing can be particularly problematic when coarse voxel data are being acquired, as in chemical shift imaging. Here, spectral information from surrounding voxels may additively or subtractively contaminate the spectrum of the volume of interest (see *Chemical Shift Imaging*).

Enhanced edge ringing can also arise from gradient problems. Eddy currents persisting into the data sampling window and nonlinear gradient amplifiers at high power can lead to enhanced apparent edge ringing. These are corrected by better amplifiers and self-shielded gradient designs (see *Gradient Coil Systems*).

4 BLACK BOUNDARIES

Figure 3 shows an image with a well-defined, single-pixel-wide, black boundary between two adjacent tissues. This black line is an artifact. It results from the custom of showing MR images as magnitude images instead of as arrays of complex numbers (see *Phase Contrast MRA*). Whenever two adjacent tissues have opposite phase, the magnitude image will present them with an artifactual black line between them. Such phase inversions can occur with inversion recovery images (see *Inversion-Recovery Pulse Sequence in MRI*), gradient echo images of fat and water, as seen in Figure 3, or motion shear between adjacent structures. Properly phased, real reconstructions serve to present the adjacent tissues in their true contrast relationship, and hence to eliminate the perception of a discrete black boundary.

These black boundary artifacts are different from the chemical shift artifact, which appears as a black boundary on one side and a bright boundary on the other side of fat/water interfaces (see *Tissue Water and Lipids: Chemical Shift Imaging and Other Methods*).

Figure 3 A gradient echo image through the thigh. The black lines between the muscle and subcutaneous fat and around the veins are artifactual black boundaries due to the fat and water signals being 180° out of phase. (Reproduced by permission of C. V. Mosby-Year Book, R. M. Henkelman, in 'Magnetic Resonance Imaging', eds. D. D. Stark and W. G. Bradley, Mosby-Year Book, St. Louis, MO, 1991, Chap. 10, p. 233)

5 STRIPING AND HERRINGBONE PATTERNS

Figure 4 shows an image with a pronounced striping artifact across it, which can be removed by correcting a single erroneous data point. When more than one data point is corrupted, the system of cross stripes gives an image with an imposed herringbone pattern. When many data points or whole data lines are corrupted, correction of the artifact using interpolation becomes less reliable.

Bad data points result from errors in the receiver analog-to-digital conversion (see *Whole Body Magnetic Resonance Spectrometers: All-Digital Transmit/Receive Systems*). Such errors may result from ADC hardware failures, but more often are caused by electrostatic shocks into the rf receiver from the patient or blankets (see *Quality Control and Quantification in Whole Body MRI and MRS*).

6 MOIRÉ FRINGES

Images can sometimes appear quite normal, except for an overlay of bright and dark alternating bands, often of irregular shape. These can be widely spaced, giving an appearance like stripes on a zebra, or can be closely spaced as in a moiré pattern of fringes. Such artifacts usually occur when two images overlap, such as occurs with aliasing, as shown in Figure 5. If the overlapping images have similar phase relationships, as in a spin echo image, they simply add. If, however, the images have a varying phase relationship, such as might occur with gradient echo imaging of anatomy in a large- B_0 inhomogeneity far from the center of the magnet, then the images will add constructively or destructively,

Figure 4 A bad data point. (a) An image with a pronounced diagonal striping across it. (b) Investigation of the k -space data from which this image was reconstructed shows a single anomalous data point (circled) at the k -space location corresponding to the frequency and orientation of the stripes. (c) Replacement of the bad data point by the average of its neighbors removes the artifact from the image. (Reproduced by permission of Pergamon Press, Elmsford, NY from R. M. Henkelman and M. J. Bronskill, *Rev. Magn. Reson. Med.*, 1987, 2, 1)

depending on the relative phase. The fringing pattern is then an interference pattern between the two images with varying phase relationship.

The situation is more subtle, but the concept is the same, when the two images are geometrically identical but are generated through different coherence pathways. This can occur, for example, in a late echo, multiple spin echo image, where the stimulated echoes arising from nonideal tip angles have been arranged to superimpose on the primary spin echo. If the accumulated phase is the same for the spin echo and stimulated echo over the whole image, the addition will be constructive; if there are regions where the phase is opposite, the image will

interfere, leading to fringes (see *Multi Echo Acquisition Techniques Using Inverting Radiofrequency Pulses in MRI; Selective Excitation Methods: Artifacts*).

Such interference fringes can be deliberately generated to provide a tagging grid for motion studies, particularly those of the heart (see *Marker Grids for Observing Motion in MRI*).

7 CENTRAL POINT ARTIFACTS

The central point of the image is unique with respect to data acquired in k -space. For k -space acquisitions that begin acquiring data from the center of k -space (see *Image Formation Methods; Projection-Reconstruction in MRI*, and *Spiral Scanning Imaging Techniques*), small errors in the time origin lead to bright or dark contrast pixels in the reconstructed image. Such central artifacts are almost the hallmark of radially acquired data. Removal of these artifacts requires careful time adjustment of the data acquisition or, equivalently, careful phasing of the reconstructed projection.

Even for rectangular data acquisitions (see *Spin Warp Data Acquisition; Partial Fourier Acquisition in MRI*, and *Echo-Planar Imaging*), central artifacts occur if the rf transmitter allows the reference rf to leak through during data acquisition. Careful blanking of the rf transmitter and amplifier during all data acquisition effectively removes these central artifacts.

8 ZIPPERS

Zippers are lines of incorrect intensity that run across the image. They often appear with alternating bright and dark signal intensity, and thus can look like a 'zipper' crossing the image. The placement and orientation of such 'zippers' can be used to distinguish their various origins.

Zippers that run in the phase-encode direction (Figure 6) at any arbitrary location in the image are due to discrete rf noise.

Figure 5 Moiré fringing patterns from interference effects between the abdominal image and aliased anatomy from beyond the boundary of the image. (Reproduced by permission of C. V. Mosby-Year Book, from R. M. Henkelman, in 'Magnetic Resonance Imaging', eds. D. D. Stark and W. G. Bradley, Mosby-Year Book, St. Louis, MO, 1991, Chap. 10, p. 233)

Figure 6 A 'zipper' of bright and dark signal intensity propagating in the phase-encode direction (vertical) is due to discrete rf noise from either the imager's computer systems or the environment that is being picked up by the NMR receiver coil. (Reproduced by permission of Pergamon Press, Elmsford, NY from R. M. Henkelman and M. J. Bronskill, *Rev. Magn. Reson. Med.*, 1987, 2, 1)

They can be identified as such by shifting the magnetic field and hence the central resonant frequency of the imager, causing the rf noise zipper to shift across the image. Elimination of rf noise requires better environmental rf shielding of the MR imager or better isolation of the imager electronics from the rf receiver chain. When better shielding is not an option, shifting the resonant frequency as described above can be used to search for a clean 'window' in which to operate the MR imager.

Another type of zipper can occur through the center of the image propagating in the frequency-encode direction. The origin of these zipper artifacts is different—they arise from free induction decay or stimulated echo signal that has not been phase-encoded and hence makes a consistent contribution to each acquired data line.⁶ These spurious signals usually arise from nonideal selective excitation pulses (see *Selective Excitation Methods: Artifacts*). As imaging methods become faster, there are greater numbers of rf pulses per T_1 interval, providing many more stimulated echo pathways that can give rise to zippers. There are three methods for reducing these artifacts:

1. design of better rf-generated slice profiles (see *Selective Excitation in MRI and MR Spectroscopy*);
2. phase cycling of alternate rf excitations to push the artifact to the boundary of the image;
3. the use of 'crusher' gradients to spoil any unwanted transverse coherence.

It should be recognized that, although the zippers discussed above are evident only in rectilinear acquisitions of k -space data, the physical principles from which they arise contribute unwanted signal to all data sampling schemes. For more elaborate data acquisition schemes, the resulting artifacts may be less recognizable and may even simply appear as 'noise'. This

does not make it any less needful to carefully eliminate artifactual signal from the desired data.

9 IMAGE DISTORTIONS AND BLURRING

The spatial mapping in MR imaging is predicated on a fixed relationship between location and frequency. If either the magnetic field is not homogenous or the imaging gradients are not linear, this relationship is violated, and the image becomes distorted in some way.

A spin, expected to have a resonant frequency of γB_0 , that has a resonant frequency of $\gamma(B_0 + \Delta B_0)$ because of a field inhomogeneity ΔB_0 will be shifted from its true location in the image along the frequency-encode direction toward higher frequency by $\Delta B_0/G_x$, where G_x is the strength of the frequency encoding gradient. It should be noted that phase encoding does not exhibit a similar displacement (see *Spin Warp Data Acquisition*). Therefore, phase encoding in all three directions is an effective, although unrealistically slow, method to avoid magnetic field inhomogeneity distortions.

Magnetic field inhomogeneities may also be caused by magnetic susceptibility variations within the patient, as seen in Figure 7. Distortions can be minimized with increased gradient strengths and decreased acquisition bandwidths. The associated loss in signal-to-noise ratio can be recovered by judicious averaging.

Figure 7 Sagittal image of the spine of a patient with a surgically implanted metal support rod. Displacement of the spinal cord posteriorly (in the frequency encode direction) results from distortion of the main magnetic field. (Reproduced by permission of C. V. Mosby-Year Book, from R. M. Henkelman, in 'Magnetic Resonance in Medicine', eds. D. D. Stark and W. G. Bradley, Mosby-Year Book, St. Louis, MO, 1991, Chap. 10, p. 233)

Figure 8 (a) A gradient echo image from a uniform gel phantom containing a 4 mm long wire of $60 \mu\text{g}$ mass. The wire produces a dipolar field in the gel as shown in (b). The image is taken in a plane (shaded) that is parallel to the applied magnetic field and displaced from the wire. The three regions of signal loss in the image are caused by intravoxel dephasing. (Reproduced by permission of RSNA Publications, Oak Brook, IL from J. K. Kim, W. Kucharczyk, and R. M. Henkelman, *Radiology*, 1993, **187**, 735)

Even if the main field is uniform, gradient nonlinearities can produce image distortions in both the frequency *and* phase-encode directions, as well as in the slice selection direction.

Gradient nonlinearities can be mapped, and images can be rerecified using postprocessing techniques.

Magnetic nonuniformities are more problematic in *k*-space acquisitions that are not unidirectional or are not rectilinear (see *Image Formation Methods*; *Echo-Planar Imaging*; *Projection-Reconstruction in MRI*, and *Spiral Scanning Imaging Techniques*). In these data acquisition strategies, points at field inhomogeneities will be mapped to several different points in the image resulting in image blur. Blur cannot be as readily corrected by postprocessing as can simple distortion, and hence elimination at the source should be attempted using stronger gradients, suppression of off-resonant spins, or some other technique.^{7,8}

10 SIGNAL LOSS

Magnetic field variations not only result in image distortions, but also give rise to regions of signal loss (see *Susceptibility Effects in Whole Body Experiments*).

In gradient echo imaging, if the phase dispersion of signal throughout an imaged voxel exceeds 2π radians, the net signal in the image will be significantly decreased. This signal loss is said to be due to intravoxel dephasing, and is illustrated in Figure 8.

Intravoxel dephasing can be reduced by using a spin echo acquisition that refocuses the spin phases at the time of echo acquisition. It can also be reduced by using short echo times (see *Phase Contrast MRA*). It can also be improved by reducing the voxel size by moving to higher resolution images,⁹ as shown in Figure 9.

Figure 9 A single large voxel with a susceptibility-induced field gradient can be imaged in a spin echo (SE) sequence with 100% signal (left) because the dephasing at time $\frac{1}{2}TE$ is refocused at time TE . The same voxel imaged with a gradient-recalled echo (GRE) may show 0% signal due to intravoxel dephasing (middle). However, if the voxel size is halved with the same gradient echo sequence, each half-pixel shows 39% of the total signal. The intravoxel dephasing signal loss is diminished with higher resolution. (Reproduced by permission of C. V. Mosby-Year Book from R. M. Henkelman, in 'Magnetic Resonance in Medicine', eds. D. D. Stark and W. G. Bradley, Mosby-Year Book, St. Louis, MO, 1991, Chap. 10, p. 233)

Although signal loss is reduced with spin echo imaging, it cannot be eliminated when the spins are free to diffuse through the region of the inhomogeneity. Thus, diffusion-mediated signal loss in the presence of inhomogeneities cannot be refocused by a single spin echo. However, a train of π refocusing pulses will reduce the effects of diffusion-mediated dephasing, as in a Carr–Purcell sequence.

Finally, susceptibility-induced signal losses should not be thought of only as artifacts. These signal loss mechanisms are responsible for the contrast obtained in functional and diffusion imaging (see *Hemodynamic Changes owing to Sensory Activation of the Brain Monitored by Echo-Planar Imaging; Methods and Applications of Diffusion MRI*, and *Anisotropically Restricted Diffusion in MRI*).

11 IMAGE GHOSTS

Ghost images are probably the most prevalent of all MRI artifacts. Ghosts are faint replications of the image or parts of images that show the correct spatial structure, but occur at the wrong location within the field of view. Three different ghost mechanisms are discussed, which can be distinguished on the basis of the ghost's position.

11.1 Quadrature Imbalance Ghosts

Central symmetric ghosts, which are a rotation of the image by 180° about its center, result from imbalance in the two quadrature receiver channels. The quadrature signal that is recorded in MR images is intrinsically complex, consisting of real and imaginary parts that are recorded by two independent channels. If the real and the imaginary channels have slightly different gains or, if the phases of the two demodulating frequencies are not separated by exactly 90° , then quadrature imbalance ghosts may be seen. Current state-of-the-art all-digital receivers are able to eliminate these ghosts (see *Whole Body Magnetic Resonance Spectrometers: All-Digital Transmit/Receive Systems*).

11.2 Stimulated Echo Ghosts

Stimulated echo ghosts appear as inversions of the image about the center of the image in the phase-encode direction. In a multiecho sequence, the primary image signal is obtained from echoes for which the spins have remained in the transverse plane for the whole TE time, but also from stimulated echoes that may have been stored longitudinally for part of the echo times. If the stimulated echo has received some odd number ($\dots, -3, -1, +1, +3, \dots$) of addition phase encodes and refocusing pulses, the stimulated echo image will appear as an inverted ghost with respect to the primary image.

Such ghosts can be removed by crusher gradients (see Section 6), which spoil the stimulated echo signal. If it is desired to keep the stimulated echo signal, its polarity can be managed by ensuring that any applied phase encoding is rewound within the same interval between refocusing pulses¹⁰ (see *Multi Echo Acquisition Techniques Using Inverting Radiofrequency Pulses in MRI*).

Figure 10 Ghost artifacts in an image of a quality control phantom. Ghost images are displaced in the phase-encoding direction (left and right in this case). The source of these ghosts was eventually identified as a cryopump. With each stroke, a slightly magnetic piston in the cryopump was periodically shifting the main magnet field strength. (Reproduced by permission of C. V. Mosby-Year Book, from R. M. Henkelman, in 'Magnetic Resonance Imaging', eds. D. D. Stark and W. G. Bradley, Mosby-Year Book, St. Louis, MO, 1991, Chap. 10, p. 233)

11.3 Periodic Modulation Ghosts

Displacement ghosts are replicas of parts of the image displaced in the phase-encode direction. They are the commonest type of ghost, and remain a problem in the imaging of living systems. Ghost artifacts from periodic physiological motions are discussed elsewhere (see *Motion Artifacts: Mechanism and Control* and *Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control*).

Besides physiological motions, displacement ghosts can arise from any other type of periodic variation concurrent with the imaging process, as shown in Figure 10.

Examples include building vibration, alternating line current pickup, and amplifier oscillation, as well as cryopumps. Elimination of such ghost artifacts requires an identification of the causative periodic variation and its subsequent correction. Such a detective process can be very long and expensive.

Even if a temporal variation imposed on the imaging process is not periodic, it will still propagate signal into the phase-encoding direction, as indicated in Figure 11—but it will not be recognized as ghosts.

In nonrectilinear acquisitions of k -space data, there is no preferred phase-encoding direction, and misassigned signal is scattered all over the image, where it can seldom be recognized as ghosts and may simply look like noise. Nonetheless, it is still artifactual signal that must be removed if the maximum image quality is to be achieved.

Figure 11 (a) An image of a beaker of water. (b) The same image acquisition, but after the water was stirred. Even though the motion of the water is not periodic, but rather is turbulent, signal intensity is displaced in the phase-encoding direction (up and down in this case). (Reproduced by permission of Pergamon Press, Elmsford, NY from R. M. Henkelman and M. J. Bronskill, *Rev. Magn. Reson. Med.*, 1987, 2, 1)

12 WASHED-OUT CONTRAST

There is a very characteristic artifact that presents as an image with good spatial definition and no obviously displaced image structures, but for which the contrast is washed out and there appears to be a weak aura around the imaged structure, as seen in Figure 12. The cause is simple. The artifact occurs when the data acquisitions at the center of k -space exceed the range of the analog-to-digital converter (ADC). This is most likely to occur in three-dimensional data acquisitions, where the integrated signal intensity over a 256^3 acquisition typically exceeds the high-order encoded data points by 2,¹¹ pushing the dynamic range of conventionally employed ADCs.

The artifact can be corrected by repeating the acquisition with increased receiver attenuation. Alternatively, the data can be retrospectively corrected if they are simply aliased as in Figure 12. If the central data are lost, the image can still be salvaged by imposing reconstruction conditions of compact support.¹¹

Figure 12 An axial brain image (a) with washed-out contrast and aura results from acquired k -space data that have exceeded the range of the analog-to-digital converter. (b) Correction of the aliased data and subsequent reconstruction results in an artifact-free image (c)

13 INTENSITY VARIATIONS IN THE IMAGE

There are many reasons why the eventual signal intensity in an image does not correspond directly to the known spin density in the object. It is the wide variety of these artifacts that has led to the very slow development of quantitative methods in MRI (see *Relaxation Measurements in Whole Body MRI: Clinical Utility*). Three causes of intensity nonuniformity are discussed.

13.1 Slice Profile Effects

Slice-selective rf pulses are never perfect, and always exhibit some transition region through which the effective tip angle is less than that which is prescribed. While this is not a large problem for small tip angle pulses, it becomes a major source of signal intensity artifact for 180° refocusing pulses. Thus, in a slice-selective multi-echo sequence and for a phantom with an infinite T_2 , there is typically a 5–10% loss in signal for each subsequent echo due only to sequential degradation of the slice profile. This needs to be borne in mind when attempting to estimate T_2 values, since there is an apparent multiecho decay rate due to slice profile degradation.

Another cause of signal loss can come from eddy currents. If the readout gradient compensation pulse immediately precedes the refocusing 180° pulse in a spin echo sequence, and if the gradient shows an eddy current that persists throughout the 180° pulse, then the slice-selective plane of the 180° pulse will be rotated with respect to the 90° slice-selective excitation. Such a situation will provide ideal refocusing at the center of the slice, but degraded signal intensity as one moves away from the center in the frequency-encode direction.

13.2 Slice Interference Effects

The single slice nonuniformities become more complicated when multiple slices in close proximity are employed.

Because selective excitation is not perfect, selective pulses affect spins beyond the nominal boundaries of the slice. This has two consequences:

Figure 13 Sagittal head images acquired with a T_2 -weighted spin echo sequence. The image on the left is a single slice whereas that on the right is the central image from a nine-slice contiguous multislice acquisition displayed with the same window and level. The multislice image shows the decreased signal intensity from slice interference and also the degraded contrast. (Reproduced by permission from W. Kucharczyk, A. P. Crawley, W. M. Kelly and R. M. Henkelman, *Am. J.N.R.* 1988, **9**, 443, American Society of Neuroradiology, Oak Brook, IL, USA)

1. direct interference from neighboring slices causes signal reduction in each slice and variation in the average signal intensity of slices throughout a multislice block, depending on the order of slice acquisition and the gap between the slices;
2. the real-time contrast within a slice is degraded owing to interference from adjacent slices, particularly for T_2 -weighted images.¹²

This effect is illustrated in Figure 13. These consequences can be diminished with better selective rf pulses (see *Selective Excitation Methods: Artifacts*) or by leaving a slice gap between slices.

A slice interference intensity artifact that is not improved with better selectivity or slice gap is that arising from magnetization transfer effects. It has been realized that excitation and refocusing rf pulses from all neighboring slices serve to saturate the spins of the macromolecules within the slice of interest. While these spins are not directly observed in MRI because of their short T_2 relaxation times, their saturation diminishes the signal from the liquid pool that is imaged (see *Phosphorus-31 Magnetization Transfer Studies In Vivo; Magnetization Transfer Contrast: Clinical Applications*, and *Magnetization Transfer and Cross Relaxation in Tissue*).

13.3 Nonuniform Radiofrequency Fields

Image intensity variations also arise from nonuniformities in both the transmitted rf field and the receive sensitivities of the receiver coils.

Nonuniformities in the transmitted rf field were originally believed to impose the fundamental limit to high-field imaging (see *High-Field Whole Body Systems*). However, although the images show slight rf shading, excellent MR images have been obtained at 4 T in whole body systems. Slight nonuniform rf

Figure 14 Spin echo image of a homogeneous doped water phantom containing a simple closed circular copper loop of 24 mm diameter. The loop serves as a secondary rf transmitter, and hence perturbs the uniformity of the transmitted rf field. The loop also plays the part of a secondary receiver, destroying the homogeneity of the rf receiver sensitivity.¹³

intensities are seen as a left–right asymmetry on transverse abdominal images of large patients at 1.5 T.

Nonuniformities in the sensitivities of rf receiver coils are a common experience in MRI. The image nonuniformity can hardly be considered artifactual, since the smaller localized receiver coils are used deliberately to increase the signal-to-noise ratio (see *Surface and Other Local Coils for In Vivo Studies; Whole Body Machines: NMR Phased Array Coil Systems*, and *Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas*).

Finally, nonuniformities in signal intensity can arise from both changes in the transmitted rf field and the receive sensitivity when secondary rf conductors are included in the imaging field, as shown in Figure 14. Such secondary effects may become more of an issue with the further development of interventional MRI.

14 SUMMARY

MR imaging methods display a wide variety of image artifacts, some of which have been introduced in this article. All the artifactual signals arise from well-behaved and well-understood laws of physics, taking into account instrumental imperfection. Understanding the causes of MRI artifacts usually leads to ways of correcting, or at least avoiding them, so that images can be reliably interpreted with confidence.

Whole Body Magnetic Resonance: Fast Low-Angle Acquisition Methods

Axel Haase

Physikalisches Institut, Universität Würzburg, Würzburg, Germany

1 INTRODUCTION

The most frequent applications of NMR imaging are within the field of biology and medical diagnosis. The inherent problem in early clinical practice was that NMR imaging was supposed to be a time-consuming technique. However, as early as 1977, a fast NMR imaging method, echo planar imaging (EPI), was described¹ (see *Echo-Planar Imaging*). During the first decade of clinical NMR imaging, EPI was not used owing to major limitations in technical implementation. In 1985, a further fast imaging method was found, which could be immediately applied in many clinical NMR imagers, the FLASH (fast low angle shot) technique.² The two methods rely on different approaches to the fast sampling of NMR image data. The purpose of this work is to present the physical principles and different versions of FLASH-based fast NMR imaging.

A clear definition of ‘fast NMR imaging’ cannot be found in the literature. It is even more confusing that measuring times of ‘fast NMR imaging techniques’ cover several orders of magnitude from a few milliseconds to a few minutes. A definition of fast imaging can only be given in the context of the object and its time constants under investigation. Therefore, ‘fast imaging’ is understood to be ‘fast’ compared with the time constant of the physiological process of the biological object of interest. A fast imaging technique should freeze a time-dependent process to give a ‘snapshot’ of the object or the time-dependent biological function. This is the case for heart studies, when the measuring times should be less than 50 ms, or for abdominal studies, where a measuring interval of several seconds during one breath-hold is needed. For other investigations, this definition is useless (e.g., for images of joints). Here, fast imaging has a practical or economic meaning to optimize the clinical investigation and increase patient comfort (see *Whole Body MRI: Strategies for Improving Imaging Efficiency*). Therefore, a ‘fast NMR imaging’ method has to cope with all the different needs of medical diagnosis, and cannot be restricted to a single measuring time interval. FLASH-based NMR imaging techniques address this goal.

The purpose of FLASH NMR imaging is to reduce all kinds of motional artifacts, for example, heart motion, breathing, and random motion by the patient. It will offer the possibility for the study of organ functions, and organ motion.^{3,4} A further benefit is the ability to acquire multiparameter data sets within shorter time intervals, for example, three-dimensional imaging,⁵ flow velocity information, and NMR parameter imaging.⁶ A

few years after its first conception in 1985, it has become generally accepted in routine clinical practice.

2 IMAGING TECHNIQUE

The physical principle of all FLASH-based techniques is the two- or three-dimensional Fourier transform, first proposed, as ‘Fourier zeugmatography’ in 1975⁷ (see *Image Formation Methods*). The practical question is, how to sample all necessary lines in k -space as fast and efficiently as possible. First approaches for dealing with faster imaging were focused on a reduction of the number of k -space lines in partial Fourier imaging (see *Partial Fourier Acquisition in MRI*). However, this reduces the spatial resolution to a certain extent and produces (Gibbs ringing) truncation artifacts⁸ (see *Whole Body Magnetic Resonance Artifacts*). A factor of approximately two can be gained using ‘half-Fourier’ imaging, where only half of the data is sampled and the second half is filled later by software.⁹ Partial Fourier imaging can be applied in addition to all fast techniques to reduce the measuring time further.

In principle, two methods are possible to reduce the time interval of data sampling: a reduction of the repetition time TR between the acquisition of different k -space lines, or the measurement of the whole k -space using a single NMR excitation followed by a series of NMR echoes. The second possibility includes the EPI methods. We focus on the first technique. However, a reduction of the repetition time has a considerable drawback. Every excitation of an NMR signal for a special k -space line decreases the longitudinal magnetization to a lower value M_z . During the time interval TR , M_z recovers towards its equilibrium value M_0 by spin-lattice relaxation T_1 , according to

$$M_z = M_0(1 - e^{-TR/T_1}) \quad (1)$$

It can be seen that this recovery is most inefficient, as long as TR is short compared with T_1 . M_z tends to zero when the excitation flip angle is 90° . Furthermore, spin echo experiments having 180° rf refocusing pulses and separated by short TR intervals give almost zero values of M_z .

The idea of reducing the repetition time TR to short values is, however, most promising. According to the above discussion, the goal can be reached when spin echo experiments are avoided and lower flip angles are used. In 1D NMR spectroscopy low flip angles are used to speed up the experiment while retaining a high level of NMR signal. It is known that, for given TR and T_1 values, an optimum flip angle, the ‘Ernst angle’ α_E exists where the maximum signal strength per measuring time can be expected:¹⁰

$$\cos \alpha_E = e^{-TR/T_1} \quad (2)$$

Although an ‘Ernst angle’ cannot be defined under imaging conditions, where many different T_1 values can be found, the idea of using a reduced flip angle is promising.

The second need resulting from the above discussion is to avoid spin echo experiments. This is done in conventional 1D NMR spectroscopy by the acquisition of the FID signal. Under imaging conditions, the FID signal is acquired with the help of the inversion of one magnetic field gradient.¹¹ This signal is

called a ‘gradient echo’. The physical content of FLASH-based fast NMR imaging sequences is therefore fast acquisitions of gradient echoes excited by low-flip-angle NMR excitation (FLASH $\equiv$ fast low angle shot).²

3 GRADIENT ECHOES

An FID signal rapidly decreases within a few milliseconds to zero in the presence of a magnetic field gradient. A gradient is needed to encode the spatial domain in the form of frequency information. Since the gradient switching process needs a certain time interval, the FID signal is already dephased at the time when the signal should be acquired in the presence of the gradient. There exists the possibility of shifting the NMR signal to a later time interval. This is achieved by an inversion of the polarity of the gradient. This gradient inversion produces a ‘gradient echo’. The gradient echo appears at the time when the time integral of the negative $[G_-(t)]$ and positive $[G_+(t)]$ gradient pulses become equal:

$$\int_0^\tau G_+(t) dt = \int_\tau^\delta G_-(t) dt \quad (3)$$

Here the positive gradient pulse has a duration τ , and the negative gradient pulse until the appearance of the gradient echo a duration δ . Since this time integral can be changed by experimental parameters (gradient strength and timing), the time at which the gradient echo appears is under the control of the NMR expert. The time interval between the NMR excitation and the gradient echo is called the ‘gradient echo time’ TG .

The signal strength of the gradient echo is dependent on TG and the relaxation time responsible for the FID decay, T_2^* . T_2^* is much shorter than T_2 . It is known that the relaxivity $1/T_2^*$ is composed of the sum of a number of contributions:

$$\frac{1}{T_2^*} = \frac{1}{T_2} + \frac{1}{T_{2i}} + \frac{1}{T_{2s}} + \frac{1}{T_{2c}} + \dots \quad (4)$$

Here T_2 is the spin–spin relaxation time, T_{2i} is given by inhomogeneities of the main magnetic field, T_{2s} is produced by magnetic susceptibility gradients, and T_{2c} is due to the chemical shift dispersion of the NMR signal. Other field inhomogeneities, and motions within the magnet, can cause further relaxation paths.

It should be emphasized that a gradient echo signal is strongly affected by magnetic field inhomogeneities. Furthermore, a gradient echo acquired at TG often exhibits lower signal strength than a spin echo at the same spin echo time TE .

In two-dimensional Fourier gradient echo imaging, the phase-encoding gradient pulse is switched on during the negative polarity of the gradient needed for the gradient echo. The theoretical minimum gradient echo time TG is the sum of the time intervals of the slice-selective excitation pulse, inversion of the read gradient, and half of the time interval for acquisition of the gradient echo. At least two time intervals have to be reserved for the switching processes of gradients.

In summary, the minimum TG is totally hardware-dependent. Minimum values of approximately 1 ms have been achieved so far. The minimum repetition time of a gradient echo imaging experiment is approximately twice as long as TG . Therefore, measuring times of a 128×128 pixel image of

Figure 1 Dependence of the measuring time of FLASH MRI on the applied magnetic field gradient strength and switching time of the gradient pulses. Three switching time intervals are shown: 1 ms, 0.5 ms, and 0.1 ms. The curves were calculated using a 64×128 data matrix, slice thickness 5 mm and field of view 200 mm

the order of 250 ms are possible, and have been reached by many groups. However, it should be noted that the measuring time, or the minimum repetition time TR , is hardware-dependent, as can be seen in Figure 1. Increasing the gradient strength results in a decreased measuring time owing to shorter data acquisition, phase encoding, and slice selection intervals. Fast switching gradient power amplifiers further reduce TG , TR , and the measuring time.

Typical measurement parameters in whole body clinical scanners are a gradient switching time of 1 ms and a maximum gradient strength of 10 mT m^{-1} . Under these conditions, minimum repetition times of approximately 10 ms and gradient echo times of 5 ms are achieved with fast gradient echo imaging having a 20 cm field of view. In technologically advanced scanners repetition times of 3 ms and gradient echo times of 1.5 ms are possible. However, here, the gradient switching time must be in the range of $150 \mu\text{s}$ and maximum gradient strengths of at least 20 mT m^{-1} are needed.

4 SIGNAL INTENSITY

Fast repetitions of NMR excitations with short repetition times TR and low-flip-angle rf pulses need reconsideration of the signal behavior. It is known that a train of rf pulses with $TR < T_2$ generates a constant NMR signal level with an FID contribution following an rf pulse and an echo-like signal before each pulse.¹² The echo part of the signal can be destroyed by various kinds of ‘spoiling’ methods using gradient pulses¹³ or phase scrambling of the rf pulses.¹⁴ The echo part can be refocused, when all magnetic field gradient pulses are inverted in polarity after the acquisition of the gradient echo and before the next pulse.^{15,16} The signal strength is totally dependent on the method, i.e., as between the use of ‘spoiled’ or ‘refocused’ fast gradient echo imaging.

If we assume that any transverse magnetization has been spoiled between the rf pulses, the signal will behave like

$$S \propto \frac{(1 - e^{-TR/T_1}) e^{-TE/T_2^*} \sin \alpha}{1 - e^{-TR/T_1} \cos \alpha} \quad (5)$$

If we consider refocused experiments then the signal will behave like

$$S \propto \frac{(1 - e^{-TR/T_1}) e^{-TE/T_2^*} \sin \alpha}{1 - e^{-TR/T_1} e^{TE/T_2} - (e^{-TR/T_1} - e^{-TE/T_2}) \cos \alpha} \quad (6)$$

It is interesting to note how this signal behavior changes under fast imaging conditions. Here TR and TG will be much smaller than T_1 and T_2 .

For spoiled fast gradient echo imaging and large flip angles, the signal strength will behave like

$$S \propto TR/T_1 \quad (7)$$

For low-flip-angle pulses, the signal is no longer dependent on relaxation time differences, and will be dominated by spin density.

In refocused fast gradient echo imaging using large flip angles, the signal strength will behave like

$$S \propto T_2/T_1 \quad (8)$$

This parameter is relatively low in soft tissues compared with body fluids. Therefore, the most intense regions contain fluids—like CSF in the brain. Again, the signal will be dominated by the spin density contrast when using very low flip angles.

The application of fast gradient echo imaging allows great possibilities for changing the image contrast. Thus, ‘refocused’ gradient echo imaging can produce T_2 -weighted images, according to equation (8), or ‘spoiled’ gradient echo images can give T_1 -weighted images, according to equation (7), and both techniques result in ‘spin density’ images when low-flip-angle pulses are used.

The situation in the literature is rather complex, mainly because many acronyms have been used for the different contrast mechanisms in fast gradient echo imaging. Starting from the originally proposed fast gradient echo imaging using low-flip-angle pulses, FLASH, several other pulse sequences have been described using this concept:

1. ‘spoiled’ FLASH methods: (a) SPGR (spoiled GRASS); (b) spoiled FAST (Fourier acquired steady state); (c) FFE (fast field echo);
2. MPGR (multiplexed gradient refocusing) turbo methods: (a) Snapshot-FLASH, (b) Turbo-FLASH, (c) MPRAGE (magnetization prepared rapid acquired gradient echoes), (d) FSPGR (fast spoiled GRASS), (e) TFE (turbo FFE), (f) PFI (partial flip angle imaging); ‘refocused’ FLASH methods: (i) FISP (fast imaging with steady precession); (ii) GRASS (gradient recalled acquisition in steady state); (iii) FAST (Fourier acquired steady state); (iv) GFE (gradient field echo); (v) CE-FAST (contrast enhanced FAST); (vi) FEER (fast field echo with even echo rephasing); (vii) GREC (gradient field echo with contrast).

It should be kept in mind that the principal idea of all these sequences is that fast NMR imaging can be achieved using gradient inversion, low-flip-angle excitations, and the acquisition of a gradient echo either with or without refocusing of transverse magnetization. The experiment has to be performed as

fast as possible. The repetition time is only given by experimental or hardware constraints.

5 ARTIFACTS

Numerous artifacts can appear, but can be avoided in fast gradient echo imaging. The first, and not always visible, artifact can be a severe distortion of the slice profile. It has been known for many years that the slice profile is completely changed when using large flip angles and short repetition times.¹⁷ In practical slice-selective imaging experiments, the flip angle varies across the slice, resulting in an often ‘Gaussian-shaped’ slice profile. As a consequence of this effect, large flip angles are found in the center and low flip angles at the edges of the slice profile. Higher flip angles and short repetition times TR will result in a heavy saturation in the center and almost no saturation at the edges of the slice profile. Therefore, high signal intensity will be found at the borders of the slice, giving strong partial volume artifacts.

This is the case when strongly T_1 -weighted fast gradient echo images are needed, which can be measured according to the above discussion using short TR values and high flip angles in ‘spoiled’ imaging methods. It is therefore unrealistic to calculate T_1 maps from a series of strongly T_1 -weighted images.

The most prominent feature of fast gradient echo imaging is the high-intensity signal of blood flowing perpendicular to the slice orientation. This is due to an inflow of fully relaxed magnetization during TR .⁴ The enhancement of the signal intensity of flowing blood depends on imaging parameters (TR , flip angle, and slice thickness), T_1 of blood, and the flow velocity. Although this effect can be used to image blood vessels (MR angiography), it has a negative feature. Flowing spins accumulate a velocity (v)-dependent phase when flowing along a magnetic field gradient G , according to

$$\phi = \frac{1}{2} \gamma G v t^2 \quad (9)$$

where t is the time interval between the NMR excitation and read-out of the signal. As long as the velocity remains constant, a constant phase is obtained. However, if the velocity changes during the imaging experiment (e.g., owing to pulsatile flow), different phases are accumulated, leading to severe ‘flow artifacts’ of bright intensity in the phase-encoding direction. This artifact can be reduced by rephasing gradients, giving no net phase shift due to flow velocity (‘flow-compensated’ gradient pulses). A detailed discussion of flow NMR imaging and flow compensation can be found in *Whole Body Magnetic Resonance Angiography*.

All gradient echo imaging experiments suffer from the common feature of FID signals, namely, T_2^* relaxation. The above discussion shows that owing to this effect, the signal intensity depends on magnetic field inhomogeneities from various sources, and chemical shift effects. If we have a magnetic field inhomogeneity given by the gradient G within a pixel of a diameter dr , a phase spread will appear during the gradient echo time TG :

$$\phi = \gamma G dr TE \quad (10)$$

High values of ϕ give low signal intensity in gradient echo imaging. It is clear that magnetic field homogeneity effects

decrease when the spatial resolution increases and/or the gradient echo time TG decreases. Of course, this has technological limitations, because the gradient strength and gradient switching time has to be improved. This effect, often called the ‘susceptibility’ effect, appears near air–soft tissue interphases (e.g., the nasopharynx region, air-filled bowels, and lungs) (see *Susceptibility Effects in Whole Body Experiments*).

A similar effect of signal change is observed when different chemical shift values are present in one image element. From inspection of an FID signal containing two close frequency components, we know that a beat is observed, with oscillations

of the signal during T_2^* decay. At periodic times, the signal vanishes—this is often called the opposed-phase signal. If the gradient echo time TG is exactly matched to this time, no signal can be measured from a pixel where two chemical shift components with equal intensity are present. Therefore, by a careful selection of the gradient echo time TG , ‘in-phase’ or ‘opposed-phase’ gradient echo images can be measured.

Since transverse magnetization remains in fast gradient echo imaging without any spoiling, a further ‘center’ or ‘stripe’ artifact can appear. This is because residual transverse magnetization accumulates phase from step to step in 2D FT imaging.

Figure 2 A series of 2T inversion-recovery T_1 -weighted snapshot-FLASH MR images of the human brain. The slice thickness was 8 mm, the data matrix 256×256 , and the field-of-view 25.6 cm. The inversion-recovery delay increased from 162 ms (a) to 2281 ms (h). The calculated T_1 -map is shown in (i)

Figure 3 A series of 2 T T_2 -weighted snapshot-FLASH MR images of the human brain. The slice thickness was 8 mm, the data matrix 256×256 , and the field-of-view 25.6 cm. The spin echo delay 2τ in the magnetization preparation pulse sequence $90^\circ-\tau-180^\circ-\tau-90^\circ$ increased from 1.7 ms (a) to 281.7 ms (e). The calculated T_2 -map is shown in (f)

This gives a phase-encoding modulation of the signal, with low-frequency components giving a bright phase-encoding artifact in the middle of the image. The artifact can be reduced when low flip angles are used to minimize the transverse magnetization. Otherwise, either experiments with good spoiling should be selected, or random gradient spoiling, or random variation of the phase of the rf excitation pulse used.

6 QUANTITATIVE IMAGING

Fast NMR imaging should have a well-defined image contrast, and should give quantitative NMR images of relaxation times, diffusion constants, and flow velocities. However, as pointed out above, it is difficult to observe well-defined image contrast, and even more difficult to image quantitative data using fast gradient echo sequences. For example, T_1 contrast suffers from slice profile artifacts, T_2 contrast is not obtainable using 'spoiled sequences', and a mixture of T_1 and T_2 information is given by 'refocused methods'. Furthermore, flow and diffusion information needs longer gradient echo times, with adverse effects arising due to 'susceptibility artifacts'. This problematic situation changed completely when 'magnetization prepared' fast gradient echo sequences appeared. These are called 'snapshot', 'turbo', or 'MP (magnetization prepared)' gradient echo sequences.⁶

These methods gain from the fact that, because of hardware improvements, short repetition times of 5 ms or less have become possible in whole body scanners. Now, the total measuring time is less than 1 s, and therefore comparable to an average T_1 relaxation time in high magnetic fields. Magnetization preparation means that the longitudinal magnetization can be changed in a definite way before the acquisition of the whole snapshot image. The image contrast will then be dependent on the 'magnetization preparation', because this lasts for a few T_1 intervals (typically, one to three times T_1).

Magnetization preparation can be performed using a single inversion pulse for IR T_1 -weighted images, a 90° - τ - 180° - τ - 90° (DEFT) pulse for spin echo T_2 -weighted images ($\tau = \frac{1}{2}TE$), or a DEFT pulse combined with diffusion or flow-encoding gradients for diffusion- or flow-weighted images. This technique does not suffer from all the artifacts described previously, and gives true quantitative image data when a series of images are acquired.⁶

Figure 2 shows a series of inversion-recovery T_1 -weighted snapshot-FLASH cross-sectional images of the human brain measured at 2 T magnetic field strength. These images present a sufficient data base for quantitative evaluation of a relaxation time (T_1) image. In Figure 2(i), a calculated T_1 image is shown using the images in Figure 2(a) to 2(h). The method is further demonstrated in Figure 3, where different T_2 images are displayed. The T_2 -weighting was performed using a 90° - τ - 180° - τ - 90° magnetization preparation pulse sequence. The echo times, 2τ , increased from 1.7 ms to 281.7 ms. Figure 3(f) shows the calculated T_2 -map.

7 APPLICATIONS AND CONCLUSIONS

A multitude of different applications have been described in the past few years since the beginning of fast gradient echo ex-

periments. One of the most prominent applications is in the field of rapid 3D NMR imaging. Here, the total measuring time can be limited to a few minutes, and it remains a practical method for medical diagnosis. Recent software and computer improvements have helped to increase the importance of 3D NMR imaging.

A further principal application is in the field of 'functional' NMR imaging. From the beginning, dynamic contrast media studies were very helpful in organ studies. The time resolution in fast gradient echo imaging is of the order of a few seconds. The time course of a bolus injection of an NMR contrast medium can be followed easily, and kinetic data calculated. This was first done for kidney and liver studies, and later for functional NMR imaging in the brain. However, it should be emphasized that dynamic fast gradient echo imaging using contrast media acquires a time-dependent dynamic signal change. As discussed above, the signal of fast gradient echo images has a complex dependence on various parameters—relaxation times, susceptibility, etc. Therefore, the signal intensity is not clearly related to the local concentration of a contrast medium, and is strongly dependent on the imaging experiment and parameters used. It should be emphasized that quantitative data have to be acquired for quantitative contrast media studies.

The importance and applications of fast gradient echo sequences will—as in the past—gain further from hardware improvements. An important parameter in this respect is the gradient echo time. All adverse artifacts can be reduced and the signal intensity improved when this parameter is minimized. This improvement should also help with the implementation of more 'hybrid' fast imaging sequences. In a few cases, hybrids between EPI and fast gradient echo imaging can be of advantage. The ultimate limit of all fast imaging sequences, however, is not given by technological constraints but by biological effects due to nerve stimulation in rapidly switched magnetic fields.

Whole Body MRI: Strategies for Improving Imaging Efficiency

Felix W. Wehrli

University of Pennsylvania Medical School, Philadelphia, PA, USA

1 INTRODUCTION

Since the inception of clinical MRI at the beginning of the 1980s, the rate at which a subject can be scanned has been reduced by nearly an order of magnitude. Some of the improved scan efficiency is unrelated to a shortening of the actual data acquisition time and can be accounted for by improvements in some of the ancillary procedures such as patient set-up, rf coil placement, scan parameter entry, prescan (MRI jargon for rf carrier selection and adjustment of transmit and receive gain), and advances in digital system architecture (shortening in reconstruction times, concurrence of data acquisition and reconstruction, etc.). The focus of this article, however, will be on techniques for reducing data acquisition time, since it is this that determines patient tolerance. Scan times in excess of 5–10 min typically lead to image degradation from subject motion. Another strong motivation for shortening scan time is physiologic motion such as cardiac pulsation, respiration, and peristalsis. Clearly, if the data acquisition time could be lowered below the period of physiologic motion, the effect of motion unsharpness in the image data could effectively be suppressed. Many of the new applications, such as the assessment of organ function by monitoring the passage of a bolus of contrast agent,¹ the measurement of microcirculation,^{2,3} or the study of brain function^{4–6} demand temporal resolution on the order of 0.1–1 s (see also *Contrast Agents in Whole Body Magnetic Resonance: An Overview*).

While many of the ideas for improved scan efficiency have been in existence for some time, they have become practical only in the 1990s owing to engineering advances such as digital transceiver electronics (see also *Whole Body Magnetic Resonance Spectrometers: All-Digital Transmit/Receive Systems*) and gradient technology (see *Gradient Coil Systems*). A case in point is echo planar imaging (EPI), which was first conceived in 1977,⁷ but has only recently become commercially available. It is fair to say that the gradient system drives the modern imager's performance in that data acquisition rate (and thus imaging speed) are largely determined by the gradients' amplitude, slew rate, and duty cycle. Today, most imagers are equipped with whole-body gradients providing amplitudes and slew rates in excess of 20 mT m⁻¹ and ≥ 150 T m⁻¹ s⁻¹, respectively. More recently, clinical systems with gradient strengths up to 40 mT m⁻¹ have become commercially available.⁸

This chapter briefly reviews the concepts underlying the most important classes of rapid imaging techniques, each of which is discussed in more detail in other articles in this volume. The subject of high-speed imaging has been covered by a number of specialized texts. Haacke et al. have treated the subject of short repetition time (TR) gradient-echo imaging in detail.⁹ EPI concepts have been covered by Cohen and Weisskoff¹⁰ and, more recently, in a textbook by Schmitt et al.¹¹

2 k-SPACE FORMALISM

We shall in the following resort to the classical *k*-space formalism introduced by Ljunggren¹² and Tweig.¹³ A more detailed introduction is given by Wehrli.¹⁴ In brief, data sampling occurs in reciprocal space, referred to as '*k*-space' or the 'spatial frequency domain'. For an object of spin density $\rho(\mathbf{r})$, ignoring relaxation, the spatial frequency signal $\rho'(\mathbf{k})$ is given by

$$\rho'(\mathbf{k}) = \int_{r_1}^{r_2} \rho(\mathbf{r}) e^{-i\mathbf{k}(t) \cdot \mathbf{r}} d^3r \quad (1)$$

Here $\mathbf{k}(t)$ is the spatial frequency vector, expressed in units of rad cm⁻¹:

$$\mathbf{k}(t) = \gamma \int_0^t \mathbf{G}(t') dt' \quad (2)$$

where $\mathbf{G}(t')$ is the time-dependent spatial encoding gradient in vector format. Pictorially, the spatial frequency may be regarded as the phase rotation per unit length of the object experienced by the magnetization after being exposed to a gradient $\mathbf{G}(t')$ for some period *t*.

We further recognize from equation (1) that $\rho'(\mathbf{k})$ and $\rho(\mathbf{r})$ form a Fourier transform pair, and so

$$\rho(\mathbf{r}) = \frac{1}{2\pi} \int_{k_1}^{k_2} \rho'(\mathbf{k}) e^{i\mathbf{k}(t) \cdot \mathbf{r}} d^3k \quad (3)$$

The path of the spatial frequency vector during execution of the pulse sequence is determined by the time-dependent gradient waveforms.

Since *k*-space is sampled discretely, sampling needs to satisfy the Nyquist criterion

$$\frac{1}{2} L_i k_{i,\max} = \frac{1}{2} N_i \pi \quad (4)$$

where $k_{i,\max}$ is the highest spatial frequency, L_i and N_i represent the field-of-view and number of data samples, respectively, and $i = x, y, z$. We can then write for the sampling interval Δk_i

$$\Delta k_i = \frac{k_{i,\max}}{\frac{1}{2} N_i} = \frac{2\pi}{L_i} = \frac{2\pi}{N_i \Delta L_i} \quad (5)$$

with ΔL_i representing the pixel size. The factor of 2 in equation (5) arises because we collect N_i samples from $-k_{\max}$ to $+k_{\max}$ or $\frac{1}{2} N_i$ samples from 0 to $k_{\max}$.

Since the data sampling time increases with the number of data samples, one obvious approach toward shortening the

sampling time is to reduce N_i . It is readily seen from equation (5) that this can be achieved in two different ways. If we wish to maintain the pixel size, this will result in a reduction in the field-of-view and thus an increase in Δk_i . Conversely, we may want to maintain the field-of-view, in which case Δk_i remains invariant but $k_{\max}$ is lowered, and thus pixel size is increased. In the latter case, we trade spatial resolution for a reduction in sampling time.

Further, since $\Delta k \approx \gamma \Delta t G$, the sampling interval Δt scales inversely with the amplitude of the spatial encoding gradients. Therefore, the duration of the spatial encoding process is governed significantly by the achievable gradient amplitudes. At a given resolution, the latter essentially determine what fraction of k -space can be covered following a single excitation (since the signal decays with time constant T_2). Therefore, the properties of the gradients, notably their amplitudes, and for many imaging sequences also their slew rates, are paramount in determining ultimate imaging speed.

3 CLASSIFICATION OF IMAGING TECHNIQUES

Most of the currently used imaging techniques use rectilinear k -space sampling, and as such may be regarded as descendants of the spin warp technique of Edelstein et al.,¹⁵ which itself is an outgrowth of Fourier zeugmatography, pioneered by Kumar, Welti, and Ernst.¹⁶ Since the latter is an embodiment of two-dimensional (2D) NMR spectroscopy,¹⁷ conceptionally all rectilinear sampling techniques may be regarded as originating from 2D NMR. By contrast, projection-reconstruction imaging^{18–20} or imaging with nonperiodic time-varying gradients²¹ such as spiral scanning^{22,23} are not rectilinear sampling techniques, since the k -space path is non-Cartesian.

Common to all rectilinear k -space sampling techniques are two distinct phases of spatial encoding, a first period during which a gradient G_y is applied whose time integral determines k_y , and during which no sampling occurs, followed by a second period during which a gradient G_x is applied while the free precession signal is sampled, resulting in a line $S(k_x)$. The former is typically called ‘phase encoding’ and the latter ‘frequency encoding’. In this manner, data are sampled along a 2D k -space grid by incrementally stepping the amplitude of the phase-encoding gradient. The concept can be extended to a third dimension by phase encoding along a second spatial coordinate to afford k_z , in which case k -space is three dimensional. In both back-projection and spiral scanning, two or all three spatial encoding gradients are simultaneously active while data are sampled. A generic 3D spin warp pulse sequence and k -space map are shown in Figure 1.

4 VARIOUS EMBODIMENTS OF SPIN WARP IMAGING

4.1 Scan Time, Signal-to-Noise Ratio and Spatial Resolution

Ordinarily, only a fraction of k -space is typically scanned upon creating transverse magnetization, and the process repeated multiple times, each cycle affording another k -space

Figure 1 (a) Generic 3D spin warp imaging with phase encoding on the x and y axes and frequency encoding on z . Hatched areas indicate the spatial frequency vector at time t (b). Amplitudes of phase-encoding gradients are arbitrary. During readout, a line k_x is scanned corresponding to the intersection between the (k_x, k_y) and (k_x, k_z) planes (shaded areas)

segment. Longitudinal magnetization builds up in a recurrent fashion between cycles of period TR . The data acquisition time T_{ac} scales with TR and the number of pulse sequence cycles, the latter being a function of the number of spatial encoding steps or k -space samples. It is customary to denote the frequency-encoding axis by x and the phase-encoding axis by y (or y and z , respectively, if phase encoding in an additional dimension is effected), with N_i ($i = x, y, z$) representing the number of data samples. Assuming further that during a frequency-encoding period a single line $k_{x,i=1,\dots,N_x}$ is sampled, T_{ac} to sample k -space is given by

$$T_{ac} = N_y N_z n TR \quad (6)$$

where n represents the number of sequence repetitions (also called ‘number of excitations’ in imaging jargon) at given values of k . At typical sampling rates, the sampling time for frequency encoding is on the order of 10 ms or less and so

does not appear in equation (6). It will, however, become critical in high-speed gradient echo imaging^{24,25} and EPI and its derivatives.^{26–28}

The scan time scales with the number of phase encodings (N_y in 2D, and N_y and N_z in 3D spin warp imaging), and thus a reduction in the number of phase-encoding samples entails a concomitant reduction in scan time. As previously pointed out, this can be achieved either by lowering $k_{\max}$ or by decreasing sampling density $1/\Delta k$. The former lowers resolution, the latter leads to reduced field-of-view while preserving resolution [cf. equations (4) and (5)]. Thus, the term ‘matrix size’ is ambiguous, though in common parlance a change in matrix implicitly implies fixed field-of-view. The two different situations, each lowering data acquisition time of a 3D image acquisition by a factor of 4, are illustrated in Figure 2.

Figure 2 Halving the number of phase and slice encodings (N_y , N_z) in a 3D spin warp acquisition can be achieved by reducing either the k -space area (a) or the sampling density (b), leading to lower resolution (a) or reduced field-of-view (b). Open circles represent skipped data samples

Let us now examine the signal-to-noise ratio (SNR) implications of the two different operations. The signal amplitude S scales with voxel size, i.e.,

$$S \propto \Delta x \Delta y \Delta z = \frac{L_x L_y L_z}{N_x N_y N_z} \quad (7)$$

where the product $\Delta x \Delta y \Delta z$ expresses the voxel volume; the remaining parameters have previously been defined. Further, the noise-reducing effect of sampling leads to

$$\text{SNR} \propto \sqrt{n} \quad (8)$$

and thus

$$\text{SNR} \propto \frac{L_x L_y L_z \sqrt{n}}{\sqrt{N_x N_y N_z}} \quad (9)$$

From equation (9), we conclude that halving the number of data samples N_y and N_z by halving $k_{y,\max}$ and $k_{z,\max}$ increases SNR by a factor of 2 (Figure 2a). Skipping alternate data samples, by comparison, penalizes SNR by a factor of 8 since this operation halves the field-of-view for both L_y and L_z [equation (5); Figure 2b].

4.2 Slice Multiplexing and Multiecho Acquisition

In most embodiments of 2D spin warp imaging, the period comprising slice selection, phase encoding, and frequency encoding accounts for only a fraction of the TR interval. Therefore, minimizing the dead time by shortening the pulse recycle time seems to be a straightforward means of optimizing scan time. However, TR is typically dictated by contrast requirements. Shortening of TR leads to progressive saturation, and thus, in spin echo imaging at least, is incompatible with proton density and T_2 -weighted contrast. A solution to this problem was first implemented by Crooks et al.,³⁰ leading to what is commonly called ‘2D multislice imaging’. By making the rf pulses slice selective, only the spins in the slice of interest are stimulated. Adjacent slices are then excited in sequence without perturbing the steady state. The gain in efficiency achieved in this manner depends on TR , the echo time TE , and the time required for applying the spatial encoding gradients; it typically ranges from about 10 to 50 ms. The second important innovation was the incorporation of Carr–Purcell echoes into spin warp imaging. In this manner, images with different contrast³¹ can be derived from a single acquisition. It is obvious that adding echoes reduces the number of slices that can be interrogated in a given TR period. Both 2D multislice and multiecho spin warp imaging, perhaps appearing trivial in hindsight, are, in historic perspective, among the most significant milestones in the quest for imaging efficiency.

4.3 Conjugate Synthesis

A salient property of k -space with implications for imaging speed is its conjugate symmetry, i.e.,

$$\rho(\mathbf{k}) = \rho(-\mathbf{k}) \quad (10)$$

This implies that two data samples corresponding to spatial frequencies $\mathbf{k}$ and $-\mathbf{k}$ are complex conjugates of one another. In

principle, therefore, it suffices to acquire only half of k -space. In reality, the conjugate symmetry is often not perfect. Causes of deviations are phase shifts from magnetic field inhomogeneity and motion, which require appropriate correction of the raw data before Fourier reconstruction³² (see also *Partial Fourier Acquisition in MRI*).

As already pointed out, sampling in the k_y and k_z directions is much slower than sampling in the k_x direction. Therefore, by exploiting the redundancy in phase-encoding lines, scan time is halved. Halving imaging time by conjugation was described by Margosian et al.³³ and also by Feinberg et al.³⁴ Because the phase correction requires sampling of a small number of data lines on the conjugate half, the time saving is usually somewhat less than 50%. Conjugate synthesis (also referred to as ‘half-Fourier imaging’) is particularly useful in EPI¹⁰ and single-shot RARE (rapid acquisition with relaxation enhancement) imaging (discussed below).

4.4 Variable Flip Angle Imaging

In their seminal work on pulse Fourier transform spectroscopy Ernst and Anderson³⁰ showed that for a train of equidistant rf pulses, the extent of saturation can be controlled by adjusting the rf pulse flip angle α and further that the signal peaks for the condition

$$\alpha_{\text{opt}} = \cos^{-1}(\exp^{-TR/T_1}) \quad (11)$$

where α_{opt} is the optimum pulse flip angle (also called the ‘Ernst angle’), which is valid provided that $TR \gg T_2$. It is readily recognized that flip angles $< 90^\circ$ are not compatible with the simple Hahn or Carr–Purcell imaging pulse sequence, since inversion of the residual longitudinal magnetization by the subsequent phase reversal pulse would lead to a steady state of very low magnetization. Haase et al.³⁶ modified the original spin warp technique in which a gradient echo is sampled and showed that in this manner TR could be reduced at least 10-fold relative to corresponding spin echo implementations, which may have prompted the authors to the acronym FLASH (fast low angle shot). Other solutions to the problem involve the idea to restore the longitudinal magnetization with a second 180° pulse.³⁷ An alternative solution is to select a flip angle so that $90^\circ < \alpha < 180^\circ$, followed by the usual phase-reversal 180° pulse. Since large-angle selective rf pulses are difficult to achieve, earlier work made use of composite pulses consisting of a nonselective 180° pulse followed immediately by a selective small-angle pulse of flip angle β so that $\alpha = 180^\circ - \beta$.^{38,39} The motivation for spin echoes over gradient echoes is their relative insensitivity to background gradients since, in contrast to FLASH, the signal is attenuated as $\exp(-TE/T_2)$ rather than $\exp(-TE/T_2^*)$. Recent progress in rf pulse design have led to highly selective large-angle pulses that provide superior partial flip-angle imaging. The technique has been referred to as FLASE (fast large-angle spin echo).⁴⁰

The FLASH signal can readily be calculated from the Bloch equations to yield

$$S(TR, \alpha, TE) \propto \frac{1 - \exp(-TR/T_1)}{1 - \cos \alpha \exp(-TR/T_1)} \sin \alpha \times \exp(-TE/T_2^*) \quad (12)$$

For $\alpha = \alpha_{\text{opt}}$, equation (12) simplifies to

$$S_{\alpha_{\text{opt}}}(TE) \propto \tan(\frac{1}{2}\alpha) \exp(-TE/T_2^*) \quad (13)$$

The assumption implicit in equation (12), i.e., $TR \gg T_2$ between successive rf pulses, is usually invalid at high pulse-repetition rates. As first described by Carr,⁴¹ a steady-state situation arises for spins subjected to a train of rf pulses in inhomogeneous magnetic fields, with magnetization building up in a recurrent fashion from cycle to cycle. Such a stream of equidistant rf pulses forms two signals: a free induction delay (FID) and an echo. The FID follows the rf pulse whereas the echo builds up prior to the next rf pulse, reaching a maximum at the time of the pulse.⁴² Both signals have been observed by various embodiments of gradient echo imaging, provided that the gradient moments are partially or fully balanced. In spin warp imaging, however, neither condition is ordinarily satisfied, since the phase-encoding gradient is stepped in an incremental fashion. The ensuing cycle-dependent phase shifts cause intensity artifacts that have a positional dependence, since the phase depends on the spins’ location on the phase-encoding axis.⁴³ If, however, the phase imparted by the phase-encoding gradient is unwound by a gradient of opposite moment prior to the next-following rf pulse,^{43,44} the spatial dependence of the steady state vanishes and the FID is observed. Common acronyms for this modification to the generic FLASH pulse sequence are GRASS (gradient recalled acquisition in the steady state) and FISP (fast imaging with steady state precession). It is also possible to dephase the FID and to observe the echo, although this pulse sequence has not found widespread application.⁴⁵

Finally, it is possible to design the pulse sequence such that both, FID and echo, occur simultaneously, which is the case when the gradients on all three axes are fully balanced, i.e. when the zeroth moment for all gradients is reset at the end of the pulse-sequence interval.⁴⁶ This pulse sequence is sometimes referred to as ‘true FISP’ or ‘coherent steady-state imaging (CSS)’ (see, for example, Haacke et al., Chapter 18⁴⁷). A hallmark of CSS is the very strong enhancement of fluids (by virtue of their long T_2). True FISP has not been applied widely since it is very sensitive to off-resonance effects (e.g., magnetic field inhomogeneity). The signal amplitude is a function of the precession angle $\beta = \Delta\omega TR$, where $\Delta\omega$ is the (spatially dependent) resonance frequency offset that can lead to bands of low signal intensity across the image.⁴⁸ In the absence of off-resonance effects or, alternatively, if the spins precess an integral number of half-periods between successive excitations ($\beta = n\pi$), the steady-state transverse magnetization is given by:

$$M_y^{\text{ss}} = \frac{M_0 \sin \alpha}{(T_1/T_2 + 1) - \cos \alpha (T_1/T_2 - 1)} \quad (14)$$

If $\alpha = \pi/2$, equation (14) simplifies to

$$M_y^{\text{ss}} = M_0 \frac{T_2}{T_1 + T_2} \quad (15)$$

CSS images, therefore, enhance fluid proton signal to an even greater extent than the GRASS/FISP pulse sequence.⁴⁸

From a soft tissue contrast point of view, it is often desirable to suppress transverse coherences. Application of spoiler

gradients of varying amplitude has been found to be relatively ineffective for this purpose,⁴⁹ though schemes exist that provide some spoiling efficiency.⁵⁰ Nevertheless, a more effective means of eliminating the carry-over of transverse magnetization from previous cycles is to step the rf transmit and receive phase in constant increments from cycle to cycle. Although predicted by Crawley et al.⁴⁹ rf-spoiled gradient echo imaging was developed by Matt Bernstein and his colleagues in 1989, but, unfortunately, never published.

The contrast characteristics of the two embodiments of FLASH are substantially different. In the high-flip-angle regime, GRASS affords images in which the signal scales as given in equation (14), hence favoring fluids where $T_2 \approx T_1$ (as opposed to tissues, where $T_1 \gg T_2$). By contrast, with spoiling, the signal obeys equation (12), leading to a more T_1 -weighted appearance.

4.5 High-Speed Gradient Echo Techniques

Combination of increased sampling frequency bandwidth and fractional echo sampling with partial Fourier processing,⁵¹ reduction in the number of frequency-encoding samples, and other strategies such as truncated rf pulses permit shortening of pulse repetition times to 5 ms or less.^{24,25}

Ultrahigh-speed imaging with TR values of the order of 3 ms at typical gradient amplitudes and slew rates are now possible on clinical imagers (see, for example, Epstein et al.⁸). One of the major applications of very short TR gradient echo imaging currently is contrast-enhanced MR angiography (CE-MRA) where a 3D volume has to be imaged within a 15–30 s breath-hold period (see, for example, Prince et al.⁵² and references cited therein). This acquisition mode appears to be ideal for this application where the high repetition rate maximally suppresses signal from background tissue. At the same time, the signal from vascular protons is enhanced as a result of the drastic shortening of T_1 (~50 ms) imparted by the contrast medium. CE-MRA is performed with spoiled versions of gradient echo sequences, i.e., with complete suppression of transverse coherences.

Very recently, there has also been renewed interest in very short- TR steady-state imaging. Vasanawala et al. reported a fully balanced steady-state sequence in which the rf phase is alternated 90° in successive cycles.⁵³ In this manner, a steady state is obtained with the signal alternating between two levels and with different off-resonance properties. By judiciously selecting pulse flip angle, repetition time, and resonance offset it can be shown that lipid discrimination can be achieved in that the signal from each species is alternately suppressed and retained, thus allowing both water and fat images to be obtained in a single acquisition.

Another approach to achieve a desired contrast is to create a nonequilibrium situation by preceding the train of low-angle rf pulses by an inversion pulse for T_1 -dependent contrast^{54–56} or driven-equilibrium pulses to achieve T_2 -weighted contrast.⁵⁷ Since, in this case, the magnetization evolves during scanning of k -space, effectively filtering the data in a manner determined by the spin dynamics, the usual sequential scanning from $-k_{\max}$ to $+k_{\max}$ is not optimal. Remembering that the signal components pertaining to $k \approx 0$ contribute most to contrast, it is necessary to acquire these data at the desired time point

during magnetization evolution (e.g., when the signal from a particular tissue is nulled). These requirements can, for example, be reconciled with a k -space ordering scheme that has been called ‘centric phase encoding’,⁵⁵ in which data collection starts at k -space center and proceeds outward. This imaging mode has proven useful in situations where strong T_1 contrast sensitivity is required while minimizing undesired signal from static material and, further, high temporal resolution is needed. A case in point is perfusion imaging based on dynamic monitoring of the passage of a bolus of contrast material. Figure 3 shows a series of images of the lungs collected with IR-prepared fast gradient echo imaging a rate of 1 s^{-1} , along with the time course of the signal from which perfusion information can be obtained.⁵⁸

4.6 Segmentation of k -space and View Sharing

The need for increased scan speed is particularly stringent when imaging moving structures, the prime example being the heart. The dramatic advances in data acquisition hardware and k -space scanning and reconstruction methodology have led to an explosive growth of cardiac MRI during recent years. High-speed imaging techniques now make realtime MRI of the heart a realistic possibility (see, for example, Kerr et al.⁵⁹). Nevertheless, the speed with which the heart contracts challenges even the fastest imaging techniques. A pulse repetition time of 5 ms and collection of 128 views, resulting in a scan time of 650 ms, is more than one half of an R–R interval, i.e., far too slow to capture a particular cardiac phase. One way to deal with this problem is to divide data acquisition among several successive heart beats, which, of course, requires it to be gated to the cardiac cycle. Collecting only one view per cardiac phase would require 128 heart beats, although multiple cardiac phases can be captured in this manner. This approach is the basis of ‘cardiac cine’ imaging.^{60,61} However the minimum scan time can be considerably shortened (albeit at some cost in temporal resolution) if, instead of a single line k_y , multiple lines are scanned per cardiac phase (here a cardiac phase is regarded as an interval of tens of milliseconds during which the heart does not move significantly). This enhancement, also termed ‘segmented k -space acquisition’,⁵⁶ permits shortening of the data acquisition time in cardiac cine imaging to 16–24 heartbeats,⁶² which is within the range of a breath-hold period, thus considerably improving cardiac image quality. The temporal resolution can be further enhanced by collecting multiple gradient echoes during each TR period.^{8,63}

Temporal resolution can be further enhanced if only a limited number of views are updated for each temporal frame, the rationale being that not all spatial frequency components equally contribute to signal energy. Riederer et al. first proposed this concept,⁶⁴ calling it ‘MR fluoroscopy’ in analogy to X-ray fluoroscopy, a method used for guiding interventional procedures. Van Vaals et al. showed that by updating the central views only, while sharing the more peripheral ones, dynamic processes could be monitored with greatly increased temporal resolution.⁶⁵ In more sophisticated approaches, the frequency of temporal replacement of views is effected more gradually. While the central-most views are replaced most often, the updating frequency decreases with distance from the k -space center.⁶⁶ This approach has enabled generation of multiple 3D MRA data sets following a single contrast injection

Figure 3 (a) Dynamic contrast-enhanced images of pulmonary perfusion using inversion-recovery prepared high-speed gradient echo imaging (repetition time 3.5 ms; echo time 1.4 ms; inversion time 400 ms). Forty-five images were obtained following a 1 s bolus of gadolinium-diethylenetriamine pentaacetic acid at a rate of one per second (eight images shown). (b) Time course of the parenchymal signal. (From Hatabu et al.⁵⁸ with permission)

and allows the capture of both arterial and venous phases. Images corresponding to successive temporal frames are thus reconstructed from k -space data that are partly shared. Likewise, in segmented cardiac cine imaging, temporal resolution can be augmented by view sharing in that additional images are reconstructed by combining k -space lines from adjacent temporal phases.⁶⁷

Finally, there have been other developments enhancing dynamic scanning, unrelated to pulse sequence design. One of these exploits the potential of multiple-receiver coil arrays for speed enhancement (rather than for extending sensitivity over a larger volume). Recently, Sodickson and Manning showed that

a modulation analogous to the one caused by exposure of the magnetization to a spatial encoding gradient can be achieved by using linear combinations of the signals from multiple receive coils.⁶⁸ In this manner, they demonstrated that the number of phase encodings needed to achieve a given resolution scales inversely with the number of coils in the array.

5 MULTILINE SCANNING TECHNIQUES

All previously discussed embodiments of spin warp imaging have in common that within one pulse sequence cycle, a single

data line is sampled. Collection of additional echoes merely replicates encoding affording images of increasing T_2 weighting. An inherently more efficient approach makes use of the idea to exploit a plurality of echoes in such a manner that each echo affords a separate k_y line.

5.1 Echo Planar Imaging

The technique of EPI, in which the entire 2D encoding process could be completed during a single FID was first proposed by Mansfield in 1977. The fundamental principle underlying the technique is to oscillate the read gradient G_x in the presence of a constant gradient G_y .⁷ It is readily seen that in this manner, half of k -space is traversed in a zigzag trajectory. The difficulties in reconstructing images from only half the data and nonorthogonal sampling grids were remedied with the introduction of pre-encoding gradients and discontinuous phase encoding.^{27,28} In this manner, entire images of 64×128 data samples could be obtained in as little as 50 ms at 2 T field strength.^{28,69} For an overview of the subject, the reader is referred to a review by Cohen and Weisskoff¹⁰. The technical aspects of high-speed imaging are also covered in recent textbooks.^{11,47,70} (See also *Echo-Planar Imaging*.)

An interesting corollary of single-shot EPI is that the pulse repetition time loses its meaning, since the data are collected in single sequence cycle. However, concatenation of individual acquisitions for the purpose of generating movies, for example, underlies the same restrictions as the conventional FLASH method, demanding adjustment of the rf flip angle to control saturation. Cohen and Weisskoff showed 16-frame cardiac movies obtained by acquiring complete images every 67 ms within a single heart beat.¹⁰ Unlike gated techniques, where each image data set, or fraction thereof, is collected during consecutive heart beats, the method is insensitive to variations in heart rate. In contrast to the high-speed FLASH-type methods, however, EPI puts more stringent demands on instrumentation, in particular to amplitudes and slew rates of the gradients, which explains its currently limited diffusion. Some of these conditions are relaxed if only a fraction of k -space is scanned from a single echo train. More recent work, however, demonstrates that hybrid techniques involving k -space coverage during multiple heart beats, provide better image quality.

There are only two common clinical applications of single-shot EPI, both in the brain. The first is functional imaging where high temporal resolution is required and spatial resolu-

tion is of secondary importance size (see, for example, de Yoe et al.⁷¹ and references therein). The second is diffusion- and perfusion-weighted imaging as a means to characterize ischemic lesions in patients with strokes.⁷² Here, the significance is the short total acquisition time, which prevents artifacts that would arise from physiologic motion and that are exacerbated owing to the presence of the diffusion-sensitizing gradients.⁷³

One of the inherent problems of EPI lies in the disparity in sampling rate between phase-encoding and readout direction. While each echo is read out in a fraction of a millisecond (typical sampling frequency 250–500 kHz), the duration of the echo train is on the order of 50–100 ms. The technique is, therefore, sensitive to phase accumulation from off-resonant spins in the presence of magnetic field inhomogeneity, typically arising from susceptibility effects. The obvious remedy is to shorten the echo train duration, which, without compromising resolution, would demand improved gradient hardware. Alternatively, temporal resolution can be sacrificed. Instead of collecting all k -space lines from the signal of a single rf pulse, only every m th line is sampled per excitation. It, therefore, takes m separate k -space traversals to cover k -space but, in return, the echo train has been shortened m -fold.^{74,75} The dramatic reduction in off-resonance image distortion with increasing number of interleaves is shown in Figure 4. Finally, interleaved EPI can be combined with k -space segmentation, yielding a very powerful hybrid technique.^{8,63} Instead of scanning only one line k_y during each of say eight TR periods per segment, four lines are obtained by collecting four echoes. This method has been shown to be capable of acquiring 16 temporal frames in as few as four heart beats (Figure 5).

Finally, it is instructive to compare the SNR of EPI with high-speed spin warp imaging. At a given resolution three parameters contribute to SNR:

1. sampling time ($\text{SNR} \propto \sqrt{t_s}$);
2. transverse relaxation losses ($\text{SNR} \propto \exp(-TE/T_2)$);
3. the fraction of magnetization available for signal creation (determined by saturation) ($\text{SNR} \propto f(TR, T_1, \alpha)$).

The following comparison may be instructive. Suppose a typical tissue such as neural white matter is scanned at 1.5 T field strength ($T_1 \approx 700$ ms, $T_2 \approx 75$ ms). Then consider a high-speed gradient echo acquisition with 128 phase encodings and 2 ms readout time, $TR = 5$ ms, $TE \approx 0$, operated at the optimum flip angle, which is 6.8° , and compare it with a single

Figure 4 Dependence of magnetic field uniformity-induced image distortions on the number of k -space traversals used for scanning k -space in interleaved echo planar imaging. Number of interleaves: (a) 2, (b) 4, (c) 8, and (d) 16. (Images courtesy of General Electric Medical Systems)

Figure 5 (a) Principle of segmented k -space acquisition in cardiac cine imaging with echo planar imaging (EPI) readout: The R-R interval is divided into time periods ('segments'). During each segment multiple pulse repetitions occur, each being followed by an EPI readout during which typically four k -space lines are scanned. (b) Cine images representing 16 cardiac phases. (From Epstein et al.⁸ with permission)

shot EPI with 50 ms total sampling time, performed such that $k_y = 0$ is sampled at $TE = 30$ ms. The results are summarized in Table 1. They imply a net advantage of about a factor of 5 in favor of EPI, defeating the common notion that shortened scan time inevitably exacts a SNR penalty.

Similar arguments in favor of EPI have been put forward by Cohen and Weisskoff.¹⁰ Such a comparison, however, does not withstand more rigorous scrutiny. Suppose we were to repeat the EPI scan every 640 ms, i.e., the equivalent of the FLASH data acquisition time. This would mean that the longitudinal

Table 1 Comparison of SNR in Single Shot EPI and High-Speed FLASH

	EPI	FLASH	$\text{SNR}_{\text{EPI}}/\text{SNR}_{\text{FLASH}}$
Sampling time (ms)	50	256	0.44
Magnetization	1	0.06	16.7
exp $(-TE/T_2)$	0.67	1	0.67
Net gain			4.9

See text for assumptions.

magnetization has only incompletely recovered, therefore requiring operation at the Ernst angle, which is 65° . Doing so reduces the transverse magnetization following the rf pulse to 0.64 [from equation (13)], thus lowering the relative SNR advantage of EPI to a (still substantial) factor of 3. This disparity in SNR may be explained by the fact that in EPI transverse magnetization is recycled (rather than quenched by spoiling as in a FLASH-type pulse sequence). Therefore, it would be more appropriate to compare EPI with steady-state free-precession techniques.

5.2 RARE

In 1986, Hennig introduced the spin echo counterpart of EPI,^{76,77} initiating a development with significant impact on clinical efficiency. Surprisingly, this work did initially not elicit broad interest. The perception that the images emphasized structures with long T_2 , thereby producing significantly T_2 -weighted images, prompted Hennig to dub his technique 'RARE'. While obviously highly efficient, the extreme T_2 weighting appeared to limit the method to specialized applications such as imaging of cerebrospinal fluid.

Besides scan time reduction by up to an order of magnitude, the current widespread clinical use of the method owes its popularity to its spin echo nature, i.e., being insensitive to magnetic field inhomogeneities. Equally important, however, is the almost unlimited latitude in image contrast RARE provides if implemented in a hybrid mode with only a fraction of k -space covered per echo train. It is interesting that the possibilities for contrast manipulation of the RARE sequence were already recognized by Hennig in his 1986 paper.⁷⁶ By k -space weighting the echoes appropriately, Melki et al.⁷⁸ showed that virtually any arbitrary contrast is possible. For this purpose, they devised an algorithm for phase-encoding ordering while minimizing adverse effects from discontinuous sampling of k_y -space. For example, assigning early echoes to low spatial frequencies de-emphasizes T_2 weighting. The convolution of the data with the relaxation function, of course, may result in point spread function blurring, since high- k signals are attenuated.⁷⁹

Since each of the n echoes generates n lines k_y , the minimum data acquisition time is lowered n -fold. Nevertheless, when assessing the method's efficiency in terms of scan time per image, one has to consider that the prolonged echo train reduces the number of slice locations that can be interleaved during the dead time following data collection. For example, at an echo train length of 250 ms consisting of 16 echoes, a TR of 3 s acquisition provides fewer than 12 slice locations, rather than about 30 s for a conventional dual echo scan with a second TE of 100 ms. Therefore, the greatly improved efficiency can be traded for improved resolution (by a factor of four in linear resolution) without adversely affecting SNR when compared with single line spin-echo imaging. Further, it enables 3D imaging with all its benefits such as retrospective data rearrangement with image display in secondary planes, which was hitherto impractical in spin echo imaging because of excessive scan time. An example of 3D RARE images is given in Figure 6.

Figure 6 Three-dimensional RARE (rapid acquisition with relaxation enhancement) images of the lumbar spine: (a) axial section; (b) oblique reformation showing nerve roots. (Images courtesy General Electrical Medical Systems, Milwaukee.)

Figure 7 (a) Single-shot RARE (rapid acquisition with relaxation enhancement) image acquired in 400 ms total scan time. (b) The corresponding echo planar image collected in 110 ms. Note the spatial and intensity distortions near the frontal sinuses in (b), not present in the spin echo image. (Images courtesy Dr. D. Alsop, University of Pennsylvania Medical Center.)

The logical extension of RARE, which typically requires multiple interleaves to fill k -space, is to attempt to collect all lines k_y from a single echo train, analogous to single-shot EPI. There are potential hurdles to overcome for achieving such a goal. The first is the rf heating that a closely spaced train of 180° pulses might entail, in particular in the abdomen and at high magnetic field. The second is to meet the requirement that the echoes be collected in a period short enough to avoid excessive attenuation, which otherwise can cause point spread function blurring. The first problem can be overcome by lowering the flip angle of the refocusing pulses (remembering that the power scales as the square of the flip angle), first suggested and demonstrated by Hennig.⁸⁰ One might be tempted to think that the reduction in flip angle exacts a substantial SNR penalty (just as a 90° – 90° echo has only one half the amplitude of its 90° – 180° counterpart). However, this is not the case, as has been shown both experimentally⁸⁰ and theoretically.⁸¹ In fact, Alsop demonstrated recently⁸¹ that by properly stabilizing the echo amplitude,⁸² more than 95% of the maximum signal can be recovered with 90° refocusing pulses for spins with $T_1/T_2 = 10$. The reason for this apparent anomaly lies in the contribution to the echo amplitudes from stimulated echoes. Hennig had already shown that the per-unit-time SNR of single-shot RARE can be up to a factor of 100 higher than that for conventional spin echo, which again emphasizes what we have seen for EPI, i.e., that increased scan speed does not inevitably penalize SNR.

Most single-shot RARE pulse sequences use half-Fourier reconstruction³² as a means to double resolution at a given echo train length. They are, therefore, often referred to as *half-Fourier acquisition single-shot turbo spin-echo* (HASTE).⁸³ This powerful imaging sequence has already proven its great potential in a number of applications such as imaging of the biliary system⁸⁴ or for such novel procedures as oxygen-enhanced lung ventilation imaging.^{85,86} While only slightly slower than single-shot EPI, its main benefit is its immunity to off-resonance effects (Figure 7). Like other high-speed imaging techniques, it can be combined with various magnetization preparation schemes such as inversion recovery for fat or fluid suppression (STIR and FLAIR, respectively)^{87–89} or diffusion encoding.⁹⁰

Finally, it has also been shown that RARE and EPI principles can be combined in such a manner that gradient echoes are interwoven into a spin echo train, referred to as GRASE (*gradient and spin echo*),^{91,92} and, thus, the efficiency further augmented. The counterpart of single-shot RARE is single-shot GRASE, for which high-resolution images of very good quality and contrast characteristics similar to spin echo images have been demonstrated.⁹³ The method is likely to have significant impact in instances where acquisition speed is critical but neither contrast nor resolution can be sacrificed, such as in pediatric imaging or examination of patients who would have to be sedated for more conventional imaging protocols. Lastly, similar to RARE, 3D embodiments of GRASE have been reported. Mugler showed that excellent images can be obtained with 3D GRASE if the phase-encoding order is optimized in such a manner that the point-spread function is free of side-lobes.⁹⁴ (See also *Multi Echo Acquisition Techniques Using Inverting Radiofrequency Pulses in MRI*).

6 OTHER METHODS OF SCANNING k -SPACE

An alternative k -space scanning technique that, like EPI, uses oscillating gradients is spiral MRI. As implied by the term, the k -space trajectory in this case is a spiral originating at the k -space center. Ahn et al., who published the first spiral scan images, used a back-projection algorithm for reconstruction.²² Most of the more recent work is based on constant-velocity interleaved k -space spirals (as opposed to constant angular frequency),²³ (see *Spiral Scanning Imaging Techniques*). This particular form of spiral MRI has the advantage that k -space is covered more uniformly and that the amplitude of the oscillating gradients is constant. Compared with EPI, the gradient amplitude and slew rate requirements are less demanding, and the technique has been found to be tolerant to flow-related dephasing, an observation that was attributed to the low gradient moments near the k -space center and the periodic simultaneous return to zero of all moments.²³

Spiral scans require different reconstruction algorithms. Fourier transformation along the radial coordinate affords a series of projections, from which the image is obtained by filtered back-projection.²² Alternatively, the data can be rearranged into a rectilinear grid by interpolation, thus allowing Fourier reconstruction.²³

During recent years, there has been increasing interest in spiral MRI with applications targeting realtime imaging of the heart,⁵⁹ functional imaging of the brain,⁹⁵ coronary artery imaging,⁹⁶ diffusion-weighted imaging,⁹⁷ and fast spectroscopic imaging.⁹⁸ In spiral scanning, the center of k -space is scanned first, as in radial scanning (projection imaging). Further, it has been shown that the first moment is smoothly varying over the $k_x k_y$ plane.⁹⁹ These properties render spiral images less sensitive to motion artifacts, properties which, incidentally, also apply to projection imaging.¹⁰⁰ (See also *Spiral Scanning Imaging Techniques*.)

Another non-Cartesian sampling technique suited for high-speed imaging is projection imaging, where k -space is sampled radially in two or three dimensions by simultaneous application of two or three constant-amplitude gradients that are proportional to the sine and cosine of the projection angle. In this manner, a radial path is traced, starting at the center of k -space.^{19,20} k -space is covered by stepping the gradient amplitudes so as to increment the projection angle in successive sequence cycles. By selecting shallow rf pulses, the pulse sequence can be run at rates comparable to gradient echo spin warp imaging. Since sampling can start almost immediately following excitation, the technique is particularly suited for imaging tissues with short- T_2 times such as lung parenchyma¹⁰¹ or imaging of nuclei with inherently short T_2 times such as ^{11}B .

In summary, during the past 25 years since its inception, MRI has revealed a wide spectrum of technical approaches for covering data space. Scan speed is a continuum ranging from milliseconds to minutes, with trade-offs between temporal resolution, SNR and spatial resolution. The rate at which k -space can be scanned is determined significantly by the imager's hardware, in particular the achievable amplitudes of the spatial encoding gradients and their switching rates, and the receiver's bandwidth. Besides intrinsic SNR, the ultimate scan speed may be limited by adverse bioeffects, notably peripheral nerve stimulation¹⁰³ caused at increased rates of change in the magnetic flux density (dB/dt) of the switched gradients.

Chemical Shift Imaging

Truman R. Brown

Fox Chase Cancer Center, Philadelphia, PA, USA

1 INTRODUCTION

This article describes chemical shift imaging (CSI), illustrating how useful it is as a tool for obtaining well-localized *in vivo* spectra. CSI was originally described in 1982 by Brown et al.^{1,2} A similar procedure was suggested by Maudsley et al. in 1983.³ A brief discussion of alternative localization techniques is included for comparison.

The need for a well-defined procedure for spectral localization for *in vivo* studies cannot be overemphasized. Unlike high-resolution NMR studies in chemistry, where the sample is placed entirely within a uniform rf field, studies *in vivo* are necessarily examining an inhomogeneous tissue, often with a coil which produces a spatially variable rf field. These circumstances make it very difficult to obtain a clear understanding of the relationship between observed spectra and physiology without a precise and controlled spectral localization technique: with such a technique, relationships which exist between spectral and physiological variables may be determined.

Because the wavelengths of the frequencies involved are in the 3–30 m range, no localization can be provided by the electromagnetic field directly, as in a light microscope. Instead, all localization techniques (both for imaging and spectroscopy) depend upon controlled spatial variations in either the static magnetic field or the rf magnetic field. Thus, the basic principles of localization apply equally to imaging as well as spectroscopy. The major difference is that imaging is usually concerned with localizing only a single component, generally water. In fact, the presence of two components at different frequencies, e.g. lipid and water, causes artifacts.

Spatially variable rf fields, typically arising from a surface coil,⁴ will not be discussed here although they have been used extensively. They are difficult to quantify, in spite of the fact that they make it easy to acquire spectra from relatively large volumes. With carefully controlled gradients in the rf field more precise localization can be carried out,⁵ although referencing them to the imaging gradients is difficult. We shall concern ourselves below only with static field gradients, used primarily as short phase-encoding pulses, which 'label' the spins at a particular position by giving them a well-defined rf phase, different at different locations. By collecting multiple FIDs each with a different gradient, mathematical reconstruction of the spatial distribution of the spins can be done by appropriately combining the FIDs. As shown below, this is generally accomplished by a Fourier transform (FT) to yield an estimate for the spin distribution. This is the same procedure used in MR imaging to reconstruct the phase-encode directions. The significant difference is the absence of a gradient during acquisition which allows a high-resolution spectrum to be acquired and then localized to particular regions or voxels.

In addition to localizing the positions of the spins with a short gradient pulse by phase encoding, gradients in the static magnetic field can be used with a selective rf pulse to excite only a limited region of the sample.^{6–8} In this case, localization in three dimensions is achieved by the application of multiple gradients in three orthogonal directions. Generally such frequency-selective techniques only obtain spectra from one, or at most a few, localized regions simultaneously,⁹ although complex pulse schemes do exist for multiple regions.¹⁰ Commonly used frequency-selective techniques are ISIS⁶ and STEAM,⁷ the former primarily for phosphorus and the latter primarily for proton spectroscopy. These techniques function well in localizing a single species of spin to a particular region. Because ISIS involves the addition and subtraction of different acquisitions there are some problems with motion sensitivity. However, the sizes of the localized region in phosphorus spectroscopy are generally large enough so that small *in vivo* motions are not a serious problem. As STEAM localizes the signal in a single acquisition, it does not suffer from this type of problem.

There is one artifact, however, from which all selective excitation techniques suffer. Nuclei which resonate at different frequencies are localized to different regions in space. A frequency-selective pulse will cause nuclei of different frequency to be localized to two different regions. This happens because a shift in resonant frequency of δf is the same as a shift in position of $\delta f/\gamma G$ where γ is the gyromagnetic ratio of the spins in Hz T^{-1} and G is the strength of the applied localizing gradient in mT m^{-1} . This artifact is not found in phase-encoding techniques because they only use the gradient for a short time to label the location of a spin in space with a phase factor. No frequency-selective rf is used, so no interaction with the gradient occurs and thus no frequency shift. For example, at a field of 1.5 T two nuclei, in the same or different compound separated by 20 ppm (a typical ^{31}P chemical shift), will be localized to regions shifted 1 cm with respect to each other in a gradient of 30 mT m^{-1} (twice the typical gradient available on clinical imagers before the introduction of echo planar imaging). The consequences of this can be very significant. For a cube (voxel) of side 5 cm, the two regions to which the two nuclei are localized are shifted 20% (1 cm out of 5 cm) with respect to one another in each dimension. This 20% linear shift causes nearly 50% of the two regions to be different [only $(4/5)^3 = 64/125$ of the volumes are in common]. For smaller voxel sizes the problem is even worse. For example, for a 27 cm^3 voxel ($3 \times 3 \times 3$), less than 1/3 (8/27) of the volumes would be in common. This means, for example, that much of the single voxel ^{31}P studies using these techniques need to be analyzed carefully if comparisons are being made between β -adenosine triphosphate (β -ATP) and inorganic phosphate (P_i) which are approximately 20 ppm apart.

2 THEORY OF CSI

In order to appreciate the theoretical development to follow, we need to introduce the concept of k space. This is the space of FT variables associated with the real space variables x , y , and z . This relationship is the same as that between the complementary FT variables, time and frequency. The associated variables are k_x , k_y , and k_z . The theorems of FT show that

knowledge of a function in one domain is equivalent to knowledge of a function in the other domain.¹¹ Thus, if we know $\bar{\rho}(\mathbf{k}, t)$, the spin distribution function in $\mathbf{k}$ space and time, we can obtain $\rho(\mathbf{r}, \sigma)$ the spin distribution in space and frequency. They are related by the following:

$$\bar{\rho}(\mathbf{k}, t) = \int \rho(\mathbf{r}, \sigma) e^{i\mathbf{k} \cdot \mathbf{r}} e^{i\sigma t} d\mathbf{r} d\sigma \quad (1)$$

where σ is the chemical shift (frequency) variable and a ‘bar’ represents the transformed function.

As shown below, the fundamental theorem of NMR localization states that sampling a free induction decay is equivalent to sampling the distribution of the excited spins along a particular trajectory in $(\mathbf{k}, t)$ space. It was originally proved some time ago.¹ This theorem underlines all forms of imaging with NMR.

3 FUNDAMENTAL THEOREM OF NMR LOCALIZATION

The fundamental theorem we seek to prove is that the FID of the spins in a sample in a gradient is the FT of the detectable spatial spin distribution in the sample, $\bar{\rho}_D$, evaluated along a particular trajectory in the transform space, i.e., $S(t) = \bar{\rho}_D(\mathbf{k}(t), t)$. As shown below, this trajectory in $\mathbf{k}$ space is given by the gyromagnetic ratio, γ , times the integral of the gradient in time from the beginning of the FID. That is,

$$\mathbf{k}(t) = \gamma \int_0^t \mathbf{G}(\tau) d\tau \quad (2)$$

Here $S(t)$ is the FID at time t , $\rho_D(\mathbf{r}, \sigma)$ is the detectable concentration at position $\mathbf{r}$ of a spin with chemical shift σ and $\mathbf{G}(\tau)$ is the gradient at time τ .

To prove this, consider the evolution of a single species of spins with chemical shift σ in a sample following excitation. The FID as a function of time, $S(t)$, will be the sum of the magnetization at each point $\mathbf{r}$, corrected by a sensitivity factor $D(\mathbf{r})$ and a phase factor $\phi(\mathbf{r}, t)$ which measures how much the magnetization at $\mathbf{r}$ contributes. Mathematically,

$$S(t) = \int \rho(\mathbf{r}) D(\mathbf{r}) e^{i\phi(\mathbf{r}, t)} d\mathbf{r} = \int \rho_D(\mathbf{r}) e^{i\phi(\mathbf{r}, t)} d\mathbf{r} \quad (3)$$

where $D(\mathbf{r})$ is simply the coil detection profile while $\phi(\mathbf{r}, t)$ is the rf phase of the spins at point $\mathbf{r}$ and time t . To calculate ϕ we need the expression for the frequency of the spins, ω , at $\mathbf{r}$. This is given by the instantaneous magnetic field at $\mathbf{r}$, $H(\mathbf{r}, t)$:

$$\frac{d\phi}{dt} = \omega(\mathbf{r}, t) = \gamma H(\mathbf{r}, t) \quad (4)$$

Integrating, we obtain

$$\phi(\mathbf{r}, t) = \int_0^t \omega(\mathbf{r}, \tau) d\tau = \int_0^t \gamma H(\mathbf{r}, \tau) d\tau \quad (5)$$

$H(\mathbf{r}, \tau)$ is made up of two terms, the static magnetic field H_0 and any gradient, $\mathbf{G}(t)$, which may be present.

Substituting $H(\mathbf{r}, \tau) = H_0 + \mathbf{G}(\tau) \cdot \mathbf{r}$, we find

$$\phi(\mathbf{r}, t) = \gamma H_0 t + \gamma \int_0^t \mathbf{G}(\tau) \cdot \mathbf{r} d\tau \quad (6)$$

since H_0 is constant. Substituting this into equation (3) yields

$$S(t) = \int \rho_D(\mathbf{r}) \exp \left\{ i \left(\gamma H_0 t + \gamma \int_0^t \mathbf{G}(\tau) \cdot \mathbf{r} d\tau \right) \right\} d\mathbf{r} \quad (7)$$

$$= \exp \{ i(\gamma H_0 t) \} \int \rho_D(\mathbf{r}) \exp \left(i \gamma \int_0^t \mathbf{G}(\tau) \cdot \mathbf{r} d\tau \right) d\mathbf{r} \quad (8)$$

The first part of this expression shows the phase factor of the Larmor frequency of the spins while the second can be written, using equation (2), as

$$\int \rho_D(\mathbf{r}) e^{i\mathbf{k}(t) \cdot \mathbf{r}} d\mathbf{r} = \bar{\rho}_D(\mathbf{k}(t)) \quad (9)$$

Putting the time dependence back and allowing for multiple species, we have the fundamental theorem of NMR imaging, $S(t) = \bar{\rho}_D(\mathbf{k}(t), t)$, where $\bar{\rho}_D$ is the FT in both space and frequency of the detectable spin distributions and $\mathbf{k}(t)$ is the integral of the gradient.

Thus a FID in the presence of a constant gradient G would sample the spatial FT of the distribution of detectable spins along the line $\mathbf{k} = \gamma G t$. Hence, by sampling uniformly in time, one also samples uniformly in $\mathbf{k}$ space. In fact this is what is done by the readout gradient in ordinary MRI. On the other hand, immediately following a short rectangular gradient pulse of strength G and length T_0 , the FID would sample the spatial FT of the detectable spin distribution at a fixed point in $\mathbf{k}$ space, corresponding to $\gamma G T_0$. A combination of these two approaches, namely a constant gradient in one direction and a pulse in the other, is used in standard 2D imaging to acquire a single line in $\mathbf{k}$ space. This is then repeated multiple times to acquire enough different lines in $\mathbf{k}$ space to calculate an image of the desired resolution and field of view (FOV). A CSI dataset is acquired analogously, by repeatedly acquiring multiple FIDs with gradient pulses of different strengths and directions. In CSI, unlike standard MRI, no readout gradient is employed, as the chemical shift information must be acquired in the absence of a gradient. Each FID is acquired at a single point in the $\mathbf{k}$ space domain. Therefore, for two spatial dimensions, one requires phase encoding in each dimension, whereas for 3D, three separate dimensions of phase encoding are needed. In this way, a complete sampling of $\mathbf{k}$ space can be acquired. Since the FID is acquired in the absence of a gradient except for the very early points in the FID, multiple compounds can be detected as in ordinary high-resolution pulse-acquire NMR experiments. An estimate of the original spatial and frequency distributions is then obtained by discrete Fourier transformations (DFT) in both time and space of this dataset.

Since the gradient pulse immediately follows the rf excitation, the very early time points in the FID are unusable. This can degrade broad signals if echoes are not used. On modern clinical machines the loss of the early time points is less than 1 ms, corresponding to linewidths greater than 300 Hz. This is usually broader than most peaks of interest, although certain phospholipid peaks can be observed at such widths. In such cases care must be taken in quantitation as these spectral lines can change shape as well as amplitude.

There are several properties of the DFT which are important here. First, in order to distinguish regions separated by a distance R , one needs to sample $\mathbf{k}$ space on the scale of $1/R$. This sets both the FOV, the largest distance to be distinguished needing the closest sampling in $\mathbf{k}$ space, and the spatial resolution, the smallest distance to be resolved needing the largest spread in $\mathbf{k}$ space, of the resultant distribution. Another important property is how the reconstructed distribution is related to the true one. This is well known from the standard theory of DFT¹¹ but is worth reviewing as it is so fundamental to understanding the nature of the localized spectra in CSI experiments (as well as standard MRI).

A finite sampling of $\mathbf{k}$ space produces effects on the reconstructed spatial distribution of the spins which is represented by a point spread function (psf) which mathematically describes how the reconstructed spectrum at a particular location, $\rho_{\text{rec}}(\mathbf{r})$, is related to the actual distribution, $\rho(\mathbf{r})$. This relationship takes the form of a convolution so that

$$\rho_{\text{rec}}(\mathbf{r}) = \int \rho(\mathbf{s}) \text{psf}(\mathbf{r} - \mathbf{s}) d\mathbf{s} \quad (10)$$

We now derive the form of the psf. First, from the formula of a DFT we know

$$\rho_{\text{rec}}(\mathbf{r}) = \sum_{n=-N/2}^{N/2-1} \bar{\rho}(\mathbf{k}_n) e^{-i\mathbf{k}_n \cdot \mathbf{r}} \quad (11)$$

Here, $\bar{\rho}(\mathbf{k}_n)$ is the FT of the true distribution at $\mathbf{k}_n$, assumed to range from $-(N/2) \Delta k$ to $(N/2 - 1) \Delta k$, where $\Delta k = 2\pi/L$, L being the FOV. Substituting for $\bar{\rho}(\mathbf{k}_n)$ in equation (11), we obtain

$$\begin{aligned} \rho_{\text{rec}}(\mathbf{r}) &= \sum_{n=-N/2}^{N/2-1} \left\{ \int \rho(\mathbf{r}') e^{i\mathbf{k}_n \cdot \mathbf{r}'} d\mathbf{r}' \right\} e^{-i\mathbf{k}_n \cdot \mathbf{r}} \\ &= \int \rho(\mathbf{r}') \left\{ \sum_{n=-N/2}^{N/2-1} e^{i\mathbf{k}_n \cdot (\mathbf{r}' - \mathbf{r})} d\mathbf{r}' \right\} \end{aligned} \quad (12)$$

Comparing equation (12) to equation (10), we see the psf is

$$\text{psf}(\mathbf{r} - \mathbf{s}) = \sum_{n=-N/2}^{N/2-1} e^{i\mathbf{k}_n \cdot (\mathbf{r} - \mathbf{s})} \quad (13)$$

In just 1D we find

$$\text{psf}(x - s) = \sum_{n=-N/2}^{N/2-1} e^{ik_n(x-s)} \quad (14)$$

$$\begin{aligned} &= \sum_{n=-N/2}^{N/2-1} e^{in\Delta k(x-s)} \\ &= e^{-i(N/2)\Delta k(x-s)} \sum_{j=0}^{N-1} e^{ij\Delta k(x-s)} \end{aligned} \quad (15)$$

Using the identity

$$\sum_{j=0}^{N-1} x^j = \frac{1 - x^N}{1 - x}$$

with $x = e^{i\Delta k(x-s)}$, equation (15) can be evaluated to give

$$\begin{aligned} \text{psf}(x - s) &= e^{-i(N/2)\Delta k(x-s)} \frac{1 - e^{iN\Delta k(x-s)}}{1 - e^{i\Delta k(x-s)}} \\ &= e^{-i(1/2)\Delta k(x-s)} \frac{\sin \frac{1}{2}N\Delta k(x-s)}{\sin \frac{1}{2}\Delta k(x-s)} \end{aligned} \quad (16)$$

where $e^{ix} - e^{-ix} = 2i \sin x$ has been used to simplify the expression. Putting $\Delta k = 2\pi/L$ we find

$$\text{psf}(x - s) = e^{-i\pi(x-s)/L} \frac{\sin \pi N(x-s)/L}{\sin \pi(x-s)/L} \quad (17)$$

The real and imaginary parts of this function are plotted as a function of $\Delta = x - s$ in Figure 1 for $N = 16$.

The real part has a large peak near $\Delta = 0$ with smaller oscillations extending to the edge of the FOV, L . These oscillations cause the well-known ‘sinc wiggles’ found in DFT. Depending on the original distribution $\rho(\mathbf{r})$, the reconstructed distribution $\rho_{\text{rec}}(\mathbf{r})$ will have varying degrees of mixing of signal from outside the region. Since the function is oscillatory, these are generally small but need to be kept in mind for precise work. The imaginary part arises from the asymmetric sampling around the origin in $\mathbf{k}$ space ($-N/2$ to $N/2-1$).

The full 3D psf for cubic sampling is simply the product of the 1D functions:

$$\text{psf}(\mathbf{r} - \mathbf{s}) = \text{psf}(r_x - s_x) \text{psf}(r_y - s_y) \text{psf}(r_z - s_z) \quad (18)$$

A general psf can be calculated if the k -space sampling is not uniform. However it does not generally have such a simple mathematical form. In the general case, the psf is given by

$$\text{psf}(\mathbf{r} - \mathbf{s}) = \sum_{\mathbf{k}\text{-sampled}} e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{s})} \quad (19)$$

The psf calculated above represents a cubic sampling in $\mathbf{k}$ space. Numerous authors have suggested spherical or high order polyhedral as sampling schemes which can take significantly less time to carry out the acquisition.¹²⁻¹⁴ For example, the volume of a sphere inscribed inside a cube is approxi-

Figure 1 Point spread function for a discrete Fourier transform with $N = 16$. Solid curve is real part; dotted curve is imaginary part

mately 50% that of the cube. Thus, only one-half the time is required to sample it at equal resolution. Since the primary determinant of the resolution of the psf is the maximum separation between k -space samples, such as spherical sampling will have approximately the same resolution as a cubic sampling. This has been implemented by Maudsley et al.¹⁴

Another potential advantage of CSI acquisition is the ability to vary the number of acquisitions at each point in k space. It has been shown by Brown and Nelson that a Weiner optimization, assuming constant noise at each point in k space, obtains the reasonable result that the k space should be sampled at a constant rate in regions where the signal-to-noise ratio (S/N) is high going smoothly to zero in regions where the S/N is low.¹⁵ Depending upon the precise signal-to-noise ratio in a particular experimental case, a further 10% to 20% increase in sensitivity can be gathered using this procedure.

For both acquisition time considerations and spatial resolution, one generally samples only relatively small k -space values in the CSI case compared with the MRI case. This is because the metabolites of interest are 1000- to 10 000-times lower in concentration than water protons. To achieve a reasonable S/N, resolutions must be on a 1 cm rather than a 1 mm scale length. Further, the three-dimensional sampling in k space required can take considerable time. For example, an $8 \times 8 \times 8$ three-dimensional grid requires 512 separate acquisitions; at a repetition time of 1 s, this is approximately 8 min.

The sampling also causes artifacts due to its finite extent if it is desired to reconstruct the distribution from the chemical shift information at a resolution more comparable to the standard MRI images. The typical way that this is accomplished is to zero-fill the datasets in k space, and then carry out a standard FT reconstruction. Note that the psf formalism [equation (10)] still describes how the reconstructed spectrum is related to the actual distribution since $\mathbf{r}$ can be evaluated at any point. It is clear, however, that unless two values of $\mathbf{r}$ are separated by a distance of the order of the size of the central peak in Figure 1 similar spectra will be obtained.

The freedom to choose any value of $\mathbf{r}$ for reconstruction demonstrates one of the great advantages of CSI. By obtaining information in k space the reconstructed distribution can be localized anywhere. That is to say that the psf can be centered about any point in the real space. This procedure is called voxel shifting and is accomplished by multiplying the k -space distribution by a phase factor $\exp(-i\mathbf{k} \cdot \boldsymbol{\delta})$ if we wish to shift the center of the reconstructed voxels by $\boldsymbol{\delta}$. This can be easily proven by substituting $\bar{\rho}(\mathbf{k}_n)\exp(-i\mathbf{k} \cdot \boldsymbol{\delta})$ for $\bar{\rho}(\mathbf{k}_n)$ in the derivation of the psf given above.

This, as shown in the examples below, is a particularly convenient way to reconstruct even a single localized region because no prior localization is required and if a mistake is made it is easy to recalculate a distribution with the psf centered at a different location.

There is no easy way to overcome the difficulties of reconstruction brought about by finite sampling while using standard FT reconstruction methodology. However, there are techniques which have been proposed which work in the reverse direction. Assume a particular distribution, for example, constrained to be within the head for a head examination, calculate the forward transform from real space into k space, adjust the distribution so that the FT agrees with what has been measured at the lower k -space regions while not forcing the higher k -space

values to be zero. The primary difficulty with methods of this type is the number of degrees of freedom in the distribution are much higher than the number of acquired data points, so that extra constraints must be imposed upon the distribution to produce a unique answer. A variety of methods can be used, e.g., correlation with the proton image¹⁶ or the use of maximum entropy or other regularizing functions to restrict the distribution. Thus far these techniques are still in their infancy, but they have great promise for removing unwanted psf effects. They are also computationally quite expensive; as computation speeds increase, this will be less of a problem.

Finally, the sensitivity of this procedure needs to be analyzed. To do this consider two extreme cases: all the spins concentrated in a very small region and a completely uniform distribution, both observed with N gradient steps. In the first case, the only effect of the different gradient pulses will be to cause the magnetization to have a different phase in each FID. The phase factor will be $\exp(i\mathbf{k}_n \cdot \mathbf{r}_0)$ for something located at $\mathbf{r}_0$ when the k -space point $\mathbf{k}_n$ is observed. Thus all the DFT does is cancel these phase factors, enabling the individual FIDs to add at the location $\mathbf{r}_0$ as though N acquisitions had been carried out without gradients, resulting in an increase in S/N compared with a single acquisition of $N^{1/2}$. In the other case, only one FID will have any substantial signal. This is the one with zero gradient, since, with a large uniform sample, the signal from different parts will cancel even for the smallest gradient, corresponding to $1/\text{FOV}$. In this case, when we carry out the DFT the only signal is from the $k = 0$ point and thus is constant everywhere. The noise, on the other hand, is in every acquisition and reduces the S/N, again compared with a single acquisition, by $N^{1/2}$. Another way of analyzing the uniform case is to realize that each reconstructed voxel corresponds to a volume of L^3/N and so as N increases, the spins contributing to the signal from each voxel decrease proportionally as N . Each of the N acquisitions contributes signal to the spins coming from the desired voxel, while the noise, being independent, adds incoherently. Thus, the final sensitivity is proportional to $N^{1/2}/N$ or $N^{-1/2}$, compared with a single acquisition.

As these examples make clear, the precise sensitivity factor depends upon details of the shape of the object and how its FT behaves in k space. If the resolution is increased by reducing the FOV while keeping the number of phase-encoding steps constant, the S/N will be reduced proportionately with the volume of the voxel if we are dealing with a uniform distribution. If, on the other hand, we are dealing with an unresolved bright spot, so that as the voxel gets smaller the number of spins within it stays the same, then so does the final sensitivity of that particular voxel. Alternatively, if we increase the resolution by keeping the same FOV and increasing N , then we will take more phase-encoding steps which will partially compensate for an increased resolution, of course at the expense of increased observation time.

Thus, as soon as the resolution is sufficient to begin to resolve objects into homogeneous regions, further increasing the resolution will result in substantial losses in S/N because the number of spins per resolution element drops as the cube of the voxel dimension. An equally valid analysis can be done in k space, once it is realized that the size of the FT of an object of dimension L rapidly falls to zero at k -space values greater than $1/L$. As the resolution of the sampling is increased to provide a subdivision of the uniform object, points in k

space are taken with very low signal and, thus, primarily add noise to the final result.

4 DATA ANALYSIS

One of the greatest impediments to the full application of CSI to two and three dimensions is the large size of the datasets and the hundreds of spectra which need to be analyzed. There are simply too many to be done manually; an automatic procedure is required. This problem is complicated in many cases because of the low S/N found in many *in vivo* CSI spectra. What is needed is a robust technique for peak identification and extraction from a noisy spectrum with variable baseline, the latter coming from the absence of the early time points in the FID during the period of the gradient pulse. Such a procedure was developed by Nelson and Brown and dubbed PIQABLE (Peak, Identification, Quantification, and Automatic Base Line Estimation).¹⁷ It is fully described in the original paper. Briefly it relies on a statistical estimation of the probabilities of deviation of a particular spectral region under examination from a running average background. Estimates of the standard deviation are calculated from the spectrum itself. The program eliminates regions identified as peaks from noise estimation and iterates examinations of the spectrum until no further peaks are identified. It has proven to be very successful with *in vivo* CSI datasets and is able to deal with varying backgrounds and broad noisy peaks in a robust way. However, it is time-consuming to carry out this processing on each spectrum in every CSI dataset, thus a variety of further developments have concentrated on peak detection in specified regions.¹⁸ This is carried out by either using a fixed frequency region or some type of localized peak search algorithm. Area estimates can then be made for each spectrum.

Several hundred numbers are still not easy to comprehend, so when one finishes analyzing a large number of spectra the problem as to how to represent these data is still present. Generally for two- and three-dimensional CSI data, image representations are an essential part of the analysis.¹⁹ Care should be taken to examine the actual spectra as well as these images as no programs at present can be viewed as 100% reliable in converting spectra to images. Nevertheless, as a method of obtaining an overview of the entire dataset, they are excellent. Typically, different compounds, when present, are represented in different colors; this leads to a loss of gray scale sensitivity in the eye so that in cases of high sensitivity [e.g., phosphocreatine (PCr) in a skeletal muscle] a standard black and white image should be used.

Another advantage of CSI localization is that the gradients used provide the same localizing information for both the MRI proton images as well as the CSI. Thus, the MRI image and the CSI dataset are naturally in registration; no complex transformations are necessary to map from one to the other. A direct overlay of the metabolic information onto a proton image can be done as shown in several of the figures in the next section. In addition to the local metabolite concentrations, of course, one also has information regarding the specific chemical shift frequencies. By shifting compounds which are known to be independent of intracellular conditions, such as PCr, glycerolphosphocholine, etc., different regions can be aligned in frequency with the result that extremely sharp spectra can be

observed from an entire organ by resuming the shifted spectra. Spatial maps of pH distribution, magnesium concentration, and other physiological variables which can shift the metabolite frequencies can also be constructed.

5 ACQUISITION

The details of acquisition of CSI sequences are generally straightforward on any standard clinical instrument. The results presented below have been acquired using a Siemens 1.5 T Magnetom. The primary criterion is the ability to generate three cycles of phase encoding which is possible on virtually all modern commercial clinical instruments. Other than that, all that is required is an excitation sequence followed immediately by a gradient pulse of as short duration as possible.

The strength of the gradient pulses can be calculated from FT considerations discussed in the previous sections. For example, a resolution of 3 cm requires the maximum distance between *k*-space points to be sampled, $\Delta k_{\max}$, to be $2\pi \times 1/3 \text{ cm}^{-1}$. From equation (10) this must be $\gamma G_{\max} T_0$ for a constant gradient which turns on and off instantly. Taking T_0 to be 1 ms and realizing $G_{\max}$ can be positive or negative, we find $G_{\max} = \frac{1}{2} \Delta k_{\max} / \gamma T_0 = 1/2 \times 2\pi \times 1/3 \times 1/10^{-3} \times 1/\gamma$; for ^{31}P this would be $6.07 \text{ mT m}^{-1} (\gamma = 17.24 \text{ MHz T}^{-1})$, while for protons it would be $2.47 \text{ mT m}^{-1} (\gamma = 42.38 \text{ MHz T}^{-1})$. Depending on the FOV this maximum would be divided into eight or 16 steps, corresponding to a FOV of 24 or 48 cm, respectively. Both positive and negative values in *k* space need to be acquired. This is required because a spatially dependent chemical shift image is a complex function, and thus both positive and negative *k*-space information is needed to reconstruct it properly. This is not the case in proton imaging where, with a single frequency, there is no true complex information present in the image, and thus half Fourier space sampling can reduce acquisition times by a factor of two. This is not possible in a general CSI acquisition as different frequencies at different places beat with one another and thus appear as complex functions.

Note that long times are required to cycle through the *k*-space points if three dimensions are desired. For example, a 16^3 acquisition requires 4096 acquisitions, generally requiring too long a time to be practical. It is also important to have a well-shimmed sample even using localization techniques since, for example in proton-decoupled ^{31}P spectra, the resolution required is less than 0.1 ppm in a single voxel.

One point that should be mentioned is the precise positioning of the positive and negative *k*-space samples. Because of the finite number of points required, the sampling is often done from $-N/2$ to $N/2 - 1$ or asymmetrically around the zero point in *k* space. For example, if N is 8 then $-4, -3, -2, -1, 0, 1, 2$, and 3 will be sampled on a uniform grid. In general, this is the way imaging sampling is carried out for N values of 64–512. In this case, the difference between $N/2$ and $N/2 - 1$ is quite small. However, as pointed out in the theory section, the psf in this asymmetric case has a small imaginary component due to the one extra negative *k*-space sample. Thus, in general, it is better to shift the sampling points by half of the *k*-space grid and not sample at the precise $k = 0$ point. This produces a completely real psf with no imaginary contamination. This can be significant for broad lines since the imaginary part of the

Figure 2 1D CSI experiment of a column phantom coaxial with a circular surface coil with 32 phase-encode steps. The solid curve is the theoretically expected signal. The individual peaks are the experimentally observed signal at the indicated distance from the plane of the coil

line is much wider in frequency and can thus lead to voxel contamination of a complex sort.

In addition to acquiring a single nucleus with CSI techniques, the techniques can be modified to acquire two techniques simultaneously. As shown by Gonen et al.,²⁰ at a slight cost in early dead time both phosphorus and proton acquisitions can be carried out in a simultaneous manner. This is accomplished by doing an early phosphorus excitation followed by part of the phase-encoding pulse, bringing the gradient to zero, exciting the protons, and finishing with another gradient pulse. The relative strengths of the gradient pulses are set so that the second pulse gives the proper proton FOV, while the combined pulses give a proper phosphorus FOV.

6 APPLICATIONS

The simplest illustration of CSI is one dimension. In this case a series of spectra is sufficient to demonstrate the localization and no complex processing or image presentation is needed to appreciate the result. Figure 2 shows the result from 32 phase-encode steps using a single turn circular surface coil with a cylinder phantom along the coil axis. A square, rectangular rf pulse, equivalent to 540° at the center of the coil, excited the spins. The FIDs were Fourier-transformed in both time and k space, and the resultant spectra were all phased the same. The gradient amplitudes and widths corresponded to a spacing of 5 mm for a total FOV of 16 cm. The experiment was carried out on a 1.5 T Siemens Magnetom at 25.6 MHz with inorganic phosphate in the phantom. The peak region surrounding the phosphate resonance was selected from each spectrum and displaced along the axis in Figure 2 a distance corresponding to where the spectrum was localized with respect to the coil. The signals were compared with those expected theoretically, $B_1(y) \sin \gamma B_1(y) T_0$, where $B_1(y)$ is the rf field strength at the distance y along the axis, γ is the ^{31}P gyromagnetic ratio, and T_0 is the length of the rf pulse. Since the pulse was 540° at the coil center, for the circular loop $\gamma B_1(y) T_0 = 540^\circ a^3 / (y^2 + a^2)^{3/2}$, where a is the radius of the coil. This function was calculated as a function of position (5 mm per spectrum) along the axis, scaled in the vertical direction to fit the peak heights and is plotted as the solid line in Figure 2.

As can be seen the agreement is excellent. The only adjustable parameter here was the vertical scaling of the theoretical curve. These results demonstrate the ability of CSI phase-encoding measurements to provide excellent localization in space, as would be expected from their common use in the imaging field.

In two and three spatial dimensions it becomes possible to consider alternative ways of representing this spectral information, i.e. more than simply arrays of spectra. Since we have continuous localized spectra the obvious possibility is to use an image format to represent the spatial distribution. The primary difficulty with such a procedure is the determination of the peak areas or other variables of interest from the spectra in an automatic fashion. Traditional methods of measuring area often rely on hand integration, which is unsuitable in this case since we are dealing with several hundred spectra. As discussed above, to overcome this we have developed a program, PIQ-ABLE, which is capable of nonparametrically dividing a noisy spectrum into peak regions, slowly varying background and high-frequency noise.¹⁷ This procedure can be applied automatically to the CSI spectra. The results of this analysis can then be presented as images. Because there are usually only 8×8 or 16×16 pixels at the original resolution in the data, we have found these data can be much better visualized if they have been zero-filled and spatially filtered so as to provide spatial smoothing, and then presented at 64×64 or higher resolution.

A good illustration of these techniques in two dimensions is the observation of exercise-induced changes in the high energy phosphates in human muscle. Numerous ^{31}P studies of muscle metabolism have been carried out using surface coils in order to understand the relationship between biochemical energy demand as measured by the force developed and biochemical energy supply as measured by changes in the 'high-energy' phosphates, PCr, adenosine triphosphates (ATP), and Pi which can readily be observed in a ^{31}P spectrum of muscle. The key assumption here is that one is observing changes in metabolites in the muscle which is producing the force. This is not easy to determine when only a surface coil is used for localizing the spectrum. To investigate this more carefully, CSI was used to study single finger excitation in the human forearm. A single-turn 8 cm diameter coil was placed around the forearm; the wrist was rotated to align all the major muscle groups longitudinally so that only two-dimensional localization was needed. Steady-state studies of each finger being exercised at various levels were carried out.

The full details of the study are presented elsewhere.²¹ The 2D CSI data obtained from one volunteer in this study are shown in Figures 3, 4, and 5. Figure 3 shows a cross-sectional MRI of the forearm of a volunteer with a highlighted region approximately corresponding to the *flexor digitorum profundus*. Figure 4 shows three 4×6 arrays of spectra observed at rest (left), during exercise of the index finger (center), and of the ring and little fingers (right). Careful examination of the spectra show a very different pattern of changes in PCr and Pi in the two cases. There were no changes near the surface but substantial conversion of PCr to Pi in the deeper shaded region when the index finger was exercised while the reverse was true for the ring and little fingers.

To illustrate this, the amplitudes of the Pi peaks in the two datasets have been converted into images as discussed above.

Figure 3 Axial MRI of forearm. Highlighted region indicates approximate position of *flexor digitorum profundus*

These are shown in Figure 5 overlaid on the proton image in Figure 3 for anatomical reference. As can be seen, the metabolic activation of the muscle is localized to the deep interior of the arm during index finger exercise, while the superficial regions of the arm are activated if the ring and little finger are used. These observations suggest that many surface coil studies of the forearm need reevaluation since most surface coils used in human studies are 1–2 cm in diameter and only able to observe just beneath the surface of the arm. With such a coil, a bulb squeezing exercise without special care to use only the ring and little fingers, and not the index and middle fingers, would cause a confused picture when one tries to relate changes in high-energy phosphates with changes in physiological function, for example, Pi/PCr with workload.

Significantly different results are obtained if care is taken only to measure the work produced by the ring and little finger.²² Without the localization provided by CSI there would be no way to separate the changes at the deeper level produced by the index finger from the changes at the superficial level produced by the ring and little fingers.

These techniques can be applied in three dimensions as well as two. The first example of this was the work of Cox et al.²³ who demonstrated the feasibility of the 3D technique in human livers using a surface coil. The technique is particularly useful in studying the brain where high-quality coils can be made to

Figure 4 ^{31}P spectra from the highlighted region in Figure 3 at rest (left), during exercise of the index finger (center), and of the ring and little fingers (right)

Figure 5 The image from Figure 3 (left) overlaid with a 2D CSI image calculated from the inorganic phosphate levels following excitation of only the index finger (center) and the ring and little fingers (right)

Figure 6 A histogram of the observed chemical shift of β -ATP in human brain. The data are from seven individuals and consist of measurements from 138 different voxels. The mean of the distribution is -19.03 , $SD = 0.20$, corresponding to an Mg^{2+} concentration of $128 \mu M$

encompass the entire head. Using such coils, 3D ^{31}P CSI spectra from the entire human head can be obtained with voxel sizes as small as 8 cm^3 with observation times on the order of 100 min. At lower spatial resolution, high-quality ^{31}P spectra of brain tissue can be obtained in 20–30 min.¹⁹ This enables regional measurements of pH and pMg (from the positions of the Pi and β -ATP peaks, respectively) as well as the levels of ATP, PCr, and other phosphorylated metabolites. The Mg^{2+} levels are determined by measuring the β -ATP peak position, which is well known to titrate with Mg^{2+} .²⁴ Several studies have reported the intracellular brain magnesium concentration, in both normal volunteers and patients.^{25,26} Interestingly, free Mg^{2+} levels in the brain appear to be substantially lower than in many other tissues.^{27,28} A histogram of the position of the β -ATP peak with respect to PCr (PCr = -2.52 ppm) from normal volunteers is shown in Figure 6.

The mean is approximately -19 ppm which corresponds to a free Mg^{2+} level of about $125 \mu M$ assuming a standard titration curve for brain tissue.²⁹ Interestingly this value is observed to change both in brain tumors as well as cachectic patients.³⁰ It is too early to assign significance to these changes. Although these studies can be carried out with single voxel techniques, CSI provides both a more precise localization and a distribution of Mg^{2+} values for each individual.

Recent applications of CSI also include its use in proton spectroscopy where typically 16×16 2D CSI scans through the brain have achieved excellent sensitivity with voxels sizes of the order of 1 cm^3 .^{31–34} The applications of these techniques to proton spectroscopy are now beginning to find their way into clinical use, as they have been implemented into the latest generation of the commercial MR imagers.

The effect of proton irradiation on ^{31}P spectra from the human brain is shown in Figure 7 which compares the ^{31}P spectra from a single 42 cm^3 voxel acquired in 35 min with and without proton irradiation.³⁵

It is obvious that the phosphomonoester (PME) and phosphodiester (PDE) regions of the spectrum are considerably sharpened due to the elimination of the residual proton J coup-

ling. In both cases individual peaks can be observed corresponding to phosphorylethanolamine (PE) and phosphorylcholine (PC) in the PME region, and glycerophosphorylethanolamine (GPE) and glycerophosphorylcholine (GPC) in the PDE region. In addition there is an NOE enhancement for some peaks (e.g., approximately 50% for PCr). The additional sensitivity that proton decoupling and NOE enhancement³⁶ provide has enabled metabolic images of the human brain at a resolution less than 2 cm to be constructed. Figures 8 and 9 show four coronal images of a normal volunteer and the corresponding coronal slices of the PCr intensity taken from a dataset acquired in 115 min with a voxel size of 6 cm^3 . At this resolution, the basal ganglia are observed as distinct anatomical objects. Whether this is due to changes in PCr concentrations in gray versus white water or PCr relaxation times is unknown at present.

CSI techniques have also been used to advantage in obtaining spectra from tumors observed with surface coils. Even though only a few localized spectra are needed in these cases, the ability to voxel-shift the final result to correspond as precisely as possible to the tumor location outweighs the added complexity of a 3D CSI acquisition. This is particularly true as time is always short in clinical studies and no extra time is needed in CSI to obtain the correct localization. Figure 10 illustrates this, showing a proton axial MRI of the groin of a patient with a lymphoma with two localized grids; the dotted one is the original unshifted one and the solid one after voxel-shifting to optimize the spectral localization to the tumor.

Figure 11 compares the initial and final spectra most closely centered on the tumor in each case. From the absence of PCr in the spectrum (and its presence in the surrounding muscle) the spectrum is well localized to the tumor.

Figure 7 A comparison of proton-coupled (lower) and -decoupled (upper) ^{31}P spectra from 42 cm^3 of human brain acquired in 35 min

Figure 8 MRI coronal images of the brain of a human volunteer separated by 18 mm which is the voxel dimension in Figure 9

Figure 9 Adjacent phosphocreatine CSI images of the same sections as in Figure 8. Note the increased intensity in the regions of the basal ganglia as well as the superficial muscles outside the skull. These data were acquired in 115 min at a resolution of 18 mm

Figure 10 Axial MRI of the groin of a patient with low-grade non-Hodgkin's lymphoma with two CSI localizing grids. The dotted grid is the initial one while the solid grid is voxel shifted to align a voxel over the tumor

The ^1H decoupling discussed above allows clear resolution of the PME region into two components, PE and PC, with PE dominating. Without the CSI to localize the spectrum to the tumor, such detailed information is unattainable as shown by Figure 12 which is the spectrum acquired using only the surface coil for localization in the case of the patient shown in Figure 11.

Figure 11 The localized spectra from a ^{31}P CSI measurement of the patient shown in Figure 10. The PCr in the spectrum from the initial voxel position (upper) is absent from the voxel shifted one (lower)

Figure 12 The nonlocalized FID from the patient shown in Figures 10 and 11

An important example of the use of CSI in spectral acquisition is its use in an autoshimming procedure. This is based upon CSI localization of the water proton signals to provide a field map; through a least-squares minimization procedure, this information is used to adjust the shim currents to produce the optimum magnetic field homogeneity. The procedure produces excellent field homogeneity, as illustrated in Figure 13 which shows ^1H and ^{31}P spectra following the autoshim procedure to a volunteer's head.³⁷

7 DISCUSSION

As can be seen from the previous examples, CSI localization techniques have been used in a variety of circumstances, in general with great success. Summarizing their advantages, they produce signals from the entire tissue under study with a localization function that can be shifted over the sample at will, so as to optimize for the most appropriate signal from the region under investigation. Because of the well-defined properties of the FT, the difficulties due to the absence of high k -space samples can be dealt with mathematically, albeit with some loss of spatial resolution. The sensitivity of these techniques is high, as high as generally possible to obtain with a particular coil and spin concentration. Nevertheless the techniques are not without disadvantages, the primary one being the acquisition time required since each point in k space acquired requires another acquisition. As pointed out above, three-dimensional acquisitions can be quite time-consuming, particularly if high-sensitivity protons are under study. In these cases, generally two-dimensional acquisitions are carried out. A further disadvantage is the loss of early time points during the gradient pulse. This can be a serious problem for low-strength gradients. However, with most modern commercial clinical instruments, the gradients are sufficiently strong that this gradient pulse is seldom more than 1 ms for resolutions of 1 cm or

Figure 13 The ^1H (left) and ^{31}P (right) spectra from the whole head after several iterations of a CSI automatic shimming procedure

so, and obtaining CSI voxels significantly smaller than this is inefficient because of signal-to-noise reasons. At this short a time, only peaks with linewidths larger than 300 Hz are seriously affected, although the rolling baseline caused by even a short pulse can affect precise spectral integration procedures.

And finally, of course, is the complexity of analysis. However, with available computers the transforms can be performed in only a few minutes; the problem then becomes developing automatic analysis procedures which are able to deal with these complex data structures. This has been done and it now seems clear that it is worth the effort of dealing with these more complicated sets of spatial information. What extra information do we obtain from these observations? There is little doubt that, in many circumstances, extra biochemical or physiological information can provide a much needed insight into both physiological responses, as well as clinical questions. This is becoming clearer as more commercial instruments make it practical to carry out these types of CSI studies, and thus it is reasonable to believe that with further development, and a strong push from the user community, the instrument manufacturers will provide an integrated spectroscopy examination which is capable of easy use in a clinical setting.

This chapter has presented a brief overview of CSI and its potential. The techniques discussed here should allow a major advance in observations of metabolism in different pathological conditions. Considerable effort has been expended over the last several years to follow metabolic variations of tumors during therapeutic regimens, mostly with surface coils. Stroke and myocardial infarcts have been observed with single-voxel localization techniques which are not capable of providing as broad a picture as the multi-voxel CSI techniques discussed here. With the advent of clinical instrumentation capable of implementing these techniques, a much wider set of applications should ensue over the next few years. The ability of CSI to pinpoint metabolic changes associated with pathological states or physiological variations should provide new insights into both normal and disease processes.

Without the help of Doris Spindell, Jean Fink, and Lisa Siuda the chapter would never have been completed.

Localization and Registration Issues Important for Serial MRS Studies of Focal Brain Lesions

Douglas L. Arnold and Paul M. Matthews

Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada

1 INTRODUCTION

Many applications have been reported illustrating the potential clinical utility of magnetic resonance spectroscopy (MRS) in the study of focal brain lesions. Examples of studies include those of brain tumors (diagnosis and monitoring response to therapy) using ^1H MRS¹⁻⁷ and ^{31}P MRS,^{4,8-12} defining the evolution of hypoxic/ischemic brain damage in infants¹³⁻¹⁹ and adults,²⁰⁻²⁸ characterization of the chemical pathology and progression of focal demyelinating disease,²⁹⁻⁴² and localization of lesions associated with focal epilepsy, primarily using proton,⁴³⁻⁴⁷ but also phosphorus,^{48,49} MRS. Practical exploitation of these approaches demands: (i) the demonstration of sufficient diagnostic specificity and sensitivity; (ii) proof of the cost-effectiveness relative to current clinical test batteries for the different types of pathology; and (iii) establishment of procedures to allow studies to be reproduced with identical results at different times and with different instruments and observers. Absolute quantitation of results is desirable in the long term, but is not essential in all applications.

In this article we outline important general considerations involved in making interpretable and reproducible MRS brain studies of focal lesions. The brain is a highly heterogeneous tissue including a variety of cell types, considerable anatomic and functional specialization, and (not surprisingly, therefore) regional variations in NMR-visible metabolite resonance intensities.^{32,50} Focal brain pathology is usually also anatomically, physiologically, and metabolically heterogeneous. Clinical exploitation of MRS to study focal brain lesions therefore requires that careful attention be paid to a number of fundamental problems including: (i) localization of where the magnetic resonance (MR) signals come from; (ii) registration of examinations; (iii) quantitative measurement of resonance intensities; and (iv) appropriate statistical analytical methods.

2 FUNDAMENTAL ISSUES FOR CLINICAL MRS OF FOCAL BRAIN LESIONS

2.1 Localization

The first localization problem is reliably to obtain signal only from the brain. As the fatty diploe of the skull and muscle

surrounding the brain contain substantial amounts of the same compounds that are of interest in normal or pathological brain parenchyma, the ability to obtain signals from anatomically defined regions of brain without contamination from outside the volume of interest (VOI) is important. Even small proportions of signal from these regions could lead to large inaccuracies in quantitative assessment of metabolite concentrations in brain parenchyma. For example, contamination of proton brain spectra with as little as 1% of signal from extracerebral fat in the skull and scalp would lead to pathological amounts of lipid being observed in a normal brain spectrum.

Anatomical localization within the brain must also be achieved. Careful attention must be paid to potential contamination of spectra with signal from adjacent volumes having very different metabolite concentrations. Consider the problem of obtaining metabolite measurements from periventricular white matter using proton MRS, for example: periventricular white matter has a much lower lactate concentration than does cerebrospinal fluid (CSF), but concentrations of choline, creatine, and *N*-acetylaspartate are very much higher in brain parenchyma than CSF.

There are significant limitations to real spatial resolution that can be achieved using current volume-selection protocols. Understanding the degree to which selectivity is achieved in any study is critical for proper interpretation of spectroscopic data.

2.1.1 Single Voxel Localization

There are many techniques that allow spectra to be obtained from more or less well localized volumes within the brain. Here we consider only those methods most commonly used with clinical instruments. These can be divided into two types: (i) those that observe free induction decays (FIDs) rather than spin echoes and rely on cancellation of unwanted signals from regions outside the chosen VOI; and (ii) those that exploit spin echo techniques to excite only the VOI. Both utilize selective excitation in the presence of magnetic field gradients and so are subject to chemical shift artifacts. These artifacts appear because the frequency selective excitation leads to slightly different excited volumes for different metabolites because of their different resonance frequencies.

As the T_2 of brain phosphates is relatively short, single voxel phosphorus MRS studies in vivo have generally relied on techniques in which FIDs are acquired, e.g. ISIS.^{51,52} This avoids the signal loss due to T_2 relaxation that accompanies use of spin echo localization sequences. However, these methods depend on accurate subtractive cancellation of the relatively large amount of signal originating from outside the VOI. In practice, this is achieved only imperfectly. If one considers, for example, the problem of selecting signal from a volume of the order of 10 cm^3 out of a whole brain volume of $>1000\text{ cm}^3$, it is obvious that proportionally small inaccuracies in cancellation will result in spectra that are 'contaminated' by significant amounts of signal from outside the VOI.^{53,54} More recent implementations of this approach minimize this problem by employing additional methods for suppressing signal from outside the VOI.^{55,56}

The class of localization sequences which rely on spin echo sequences provides more reliable localization, as they excite only the VOI. Recent improvements in hardware have enabled such sequences to be employed with sufficiently short echo

times to make them practical for phosphorus MRS studies without resulting in excessive signal loss or phase problems. Most proton studies of brain employ one of these sequences, most commonly either STEAM or PRESS. In proton MRS, measurement of the signal intensities of the most abundant compounds [e.g. choline (Cho), creatine (Cr), and *N*-acetylaspartate (NAA)] are less sensitive to echo time, as the T_2 values for these molecules are relatively large and they do not have complicated spin systems that cause phase modulation of their echoes. An additional advantage of these techniques in proton MRS is that it is easier effectively to suppress the large signals from water if one does not excite water from outside the VOI.

In proton studies spin echo sequences can be employed that use relatively long echo times to take advantage of the relatively long T_2 of some of the small soluble brain metabolites relative to fat of skin and skull in order to achieve improved localization and avoid problems from eddy currents generated by gradient coils. However, shorter echo times avoid the problem of phase modulation and allow the observation of additional metabolites with complicated spin systems and short T_2 times, e.g. amino acids and inositol.^{27,57,58}

2.1.2 Spectroscopic or Chemical Shift Imaging

Single voxel techniques are inherently inefficient for applications in which chemical information from different regions is to be acquired at the same time (Figure 1). More recently developed spectroscopic imaging techniques approach an effective solution to this problem (Figure 2). Spectroscopic imaging sequences achieve localization with the use of phase-encoding pulse sequences, often combined with selective excitation so as to further minimize contamination from signal from outside the VOI. Phase encoding within the plane of the spectroscopic image is not associated with the chemical shift artifacts that arise from selective excitation. Spectroscopic imaging pulse sequences obtain signal from many relatively small voxels simultaneously. However, they tend to take a longer time to acquire than a single spectrum that represents a weighted average of resonance intensities from the same total volume. This is due to the number of averages required to obtain an adequate signal-to-noise ratio in the smaller voxels and the need to sample k -space adequately using sequences that incorporate a long sampling time in the absence of a field gradient to acquire

Figure 1 MRI and single voxel MRS examination of the same lesion a few days after the examination in Figure 2. The lesion appears similar on MRI (TR 2100, TE 30, slice thickness 8 mm). A single VOI for spectroscopic examination (TR 2000, TE 272, dimensions AP (anterior/posterior) 30 mm $\times$ CC (cranio/caudal) 22 mm $\times$ LR (left/right) 22 mm) is shown (in plane) in the box on the MRI. The VOI was chosen to sample as much of the lesion as possible but still accumulate essentially all of the signal selectively from within the lesion. The apparent metabolic changes represent an average over the entire volume and are therefore intermediate between those in voxels 1 and 2 in Figure 2. Quantitative comparison of the metabolic abnormalities apparent in the single voxel and MRS imaging examinations is difficult. The MRS image can be resampled in plane to correspond to the dimensions of the single voxel VOI, but the true shape of the volume from which the signal comes remains different because different techniques were used to define the voxels (i.e. phase-encoding in the MRS imaging, and selective excitation in the single voxel examination)

Figure 2 MRI and MRS imaging examination of a large demyelinating lesion. (a) A MRI slice through the center of the lesion (TR 2100, TE 30, slice thickness 8 mm). The phase-encoding grid for the MRS image is shown superimposed on the MRI. As long as the patient's head remains still during the entire time required for acquisition of the MR and MRS images, registration of the MRS image data is maintained. The dark and dotted lines define the VOI that was selectively excited for the MRS imaging examination. (b) The MRS image through the lesion (TR 2000, TE 272, slice thickness 20 mm). Individual spectra from voxels labeled 1, 2 and 3 are shown along the bottom of the figure. The lesion is associated with low *N*-acetylaspartate and high choline and LA. Note that the metabolic changes are different in different parts of the lesion and that abnormalities extend outside the lesion as defined on the MR image

the spectroscopic information. For proton examination in humans, current approaches allow nominal localization to volumes of about $0.5\text{--}1\text{ cm}^3$ with the use of 16×16 or 32×32 phase-encoding steps (Figure 2).

Unfortunately, the relative insensitivity of phosphorus and the fact that compounds of major interest [e.g. adenosine triphosphate (ATP)] have short T_2 times, effectively limits individual voxel sizes in phosphorus MRS imaging to more than 10 cm^3 , at least at 1.5 T. The large voxel size is usually combined with a low number ($< 16 \times 16$) of phase-encoding profiles, which again tends to lead to contamination of spectra by signals adjacent to voxels.

When interpreting data from focal brain lesions it is important to appreciate that several factors cause the voxel size to be larger and less sharply defined than the nominal voxel size. It is the true shape of the excited volume that determines where

signal actually comes from and, in consequence, the nature of partial volume effects. The nominal VOIs displayed on MRI images used to plan spectroscopy acquisitions may be defined very differently by different manufacturers, e.g. by the full width at half maximum amplitude of the excitation pulse or to include 90% of the excited signal. The definition of the selected volume needs to be clearly understood in terms of the percentage of signal coming from that volume versus the percentage of signal coming from outside the volume. In the case of phase-encoded spectroscopic images, the point spread function and effects of image processing also alter the voxel contours.

Defining the relationship between the volume from which the MRS signal is originating and any anatomically defined lesion on MRI is of great importance. Large focal brain lesions such as tumors, infarcts, or demyelinating plaques show wide

pathological heterogeneity. Interpretation of the data therefore poses the analytical problem of inferring (at least qualitatively) the chemical pathology of a region within the selected volume element, taking into account partial volume effects. The effects of small differences in linear dimensions on partial volume effects are easily underestimated. For example, in a single voxel study a spherical lesion filling an operator-defined 'cube' will contribute only 50% of the signal from the cube. If the 'cube' displayed on the monitor has margins that are defined by the full width at half maximum of the selection profile, then less than 25% of the signal will actually come from the lesion. Under these circumstances, given a normal variance of measurements of the order of 10%, only the most gross changes in metabolite concentrations could ever be detected as abnormal if the metabolic abnormality is spatially coextensive with the lesion seen on the MR image. In fact, for many focal lesions metabolic abnormalities are much more extensive than the associated imaging abnormalities,²⁹ and so significant results are obtained despite an apparently unfavorable partial volume of the lesion in the VOI.

2.2 Registration

2.2.1 Definition

The process of spatial alignment of images is referred to as 'registration'. A target image or space is defined and images to be registered with that image or space are positioned and may also be 'deformed' as necessary to match the target as closely as possible. A discussion of the methods available for registration is outside the scope of this article, but can be found in the review by Evans.⁵⁹

2.2.2 The Importance of Registration

Registration of MRS examinations is important for at least three reasons. The first is that metabolic changes must be referred to anatomical pathology in the study of focal brain lesions in order to interpret the pathological significance of observed signal intensity changes. This type of registration is implicit in planning MRS volume acquisition parameters with respect to anatomical landmarks on MRI examinations (Figures 1–3). Common anatomical landmarks can be used to allow matching of spectroscopic VOIs in independent examinations of the same individual on different occasions (see Figures 2 and 3). Registration also can greatly facilitate appropriate comparisons of data collected from different individuals who may show regional variations in anatomy, by allowing matching of volumes from different individuals in a standard anatomical space.^{59–61} Finally, averaging of anatomically correlated metabolic information increases the intrinsically low signal-to-noise ratio of single examinations, thus facilitating comparisons of groups of image data sets.⁵⁰

2.2.3 Technical Considerations

Registration may be accomplished before or after acquisition. Preplanned registration is performed by defining volumes for spectroscopic data acquisition with respect to anatomical landmarks before the data are acquired. Even when this is done for planning purposes within the context of a single MR session, errors in registration can occur due to patient movement between or during acquisitions, as well as to

chemical shift artifacts when selective excitation is used. Preplanned registration of spectroscopic examinations obtained at different times requires meticulous care and has limitations in that only translations and rotations can be matched. Thus, the method is more suitable for comparisons between studies of one individual rather than between different individuals, since it cannot compensate for different head sizes and shapes. Even minor errors in registration can have serious consequences for data quantification. For example, in a three-dimensional MRS imaging examination, shifting of 1 cm³ voxels by 2 mm in the three axes would alter the contribution of the desired voxel to the observed metabolite signals by as much as 50%.

Registration after acquisition can correct for some errors in preplanned registration and can correct for differences in head size and shape.⁵⁹ However, effective application requires three-dimensional high resolution images. These are not usually generated by conventional MRI as the slices usually have relatively poor out-of-plane resolution, and significant image degradation occurs during resampling for the three-dimensional reconstruction.

For low resolution data like the MR single voxel or spectroscopic images, preplanned registration is essential. With single voxel data, changing or moving the VOI after data acquisition is not possible. Spectroscopic images permit manipulation of voxels after acquisition, but there are significant limitations. The severity of these limitations depends on whether data sets acquired are two or three dimensional. In the case of two-dimensional spectroscopic images (or multislice two-dimensional images), data must be acquired in the same plane in the studies being registered because the plane of the voxels cannot be shifted after acquisition. However, movement of voxels for registration within the plane of the slice is possible. In the case of three-dimensional spectroscopic images, translation of voxels in all three axes is feasible. Rotation of voxels is theoretically possible, but degrades an already low-resolution image.

2.3 Measurement of Resonance Intensities

To allow chemical changes measured by MRS to be useful as indices of pathology, methods for quantitative measurement of signal intensities are necessary. In contrast to usual clinical radiology, which is based on qualitative assessments of patterns of changes in signal across images, work to date suggests that few clinical applications of brain spectroscopy will involve significant qualitative chemical changes specific to particular pathologies.⁶²

There are independent (but related) problems in quantitation of signal intensities. The first major problem is to identify methods that allow accurate and reproducible measurements of signal intensities from metabolites with varying relaxation properties and concentrations in a sample volume within which there is magnetic field inhomogeneity and, therefore, complex lineshapes. The problem is complicated in phosphorus spectra and proton spectra obtained at short echo times by the presence of overlapping and very broad peaks, which make unique fitting of peaks and the baseline impossible. Quantitative measurements with proton spectra may also be complicated by signal dynamic range problems associated with the presence of large residual signals from water. Finally, there is the problem of standardization. How can a reliable means be developed for deriving true tissue concentrations from resonance signal inten-

Figure 3 Follow-up MRI and MRS imaging of the same lesion as in Figure 2 approximately 1 year later, using identical acquisition techniques. The size, position, and angulation of the spectroscopic images were also matched as closely as possible to those of the first examination (Figure 2), but such a match is difficult to perform. An additional complication to registering the images is that the lesion is much smaller and the swelling which previously enlarged the hemisphere and shifted the midline towards the other side has resolved. All these factors conspire to make it unclear what the ideal volume for a single voxel spectroscopy follow-up should be. Spectroscopic images have significant advantages in this regard because of the availability of multiple small voxels. The three spectra shown are from the three voxels that most closely correspond to the three voxels chosen in the first examination (Figure 1)

sities so that data from different machines and different sites can be compared?

2.3.1 Spectral Estimation

Several methods are available for modeling either the FID or the Fourier transformed data.^{63–65} The methods are generally constrained to models with limited numbers of components and generally to simple relaxation behavior as expected in a homogeneous field. These assumptions are not always well founded. Even assuming that pathological states can be modeled in the same way as normal tissue may be problematical. The nature of the constraints used in models can, in principle, significantly bias results. Differences in constraints or starting values between different clinical MRS centers could therefore be expected to limit the comparability of results. Assessment of precision of the methods is straightforward, but accuracy is dif-

icult to evaluate because phantom systems for testing are inherently less complex physical structures than the brain.

The signal-to-noise ratio is relatively low in clinical spectra, further complicating all approaches to quantitation. The apparent signal-to-noise ratio is routinely improved by a variety of processing procedures. Signal processing can also be used to flatten baselines distorted in various ways. Effects of this processing on quantification of spectra must be taken into account.

Another problem is automation of quantitation methods. Automation facilitates evaluation by making it possible to deal with large numbers of spectra acquired in spectroscopic imaging studies. Use of prior knowledge and models facilitates automatic fitting, but introduces biases. However, these are at least consistent biases that are inherently more independent of operator bias than manually supervised methods, although they may differ between different sites if different models and approaches are used.

2.3.2 Relative and Absolute Quantification

Metabolite signal intensities from pathological tissue will not, in general, be useful alone. Many factors that vary from instrument to instrument, between individuals, and even during a prolonged examination determine observed signal intensities. Among them, coil quality, coupling of the sample to the coil, field (B_1) inhomogeneity, and relaxation times are the most important general factors. Most approaches to controlling for variability in coil responses and coupling involve use of an external (relative to the patient) standard. To be done rigorously, the process is quite complicated. Fortunately, modern instrumentation is generally stable enough for practical methods to work. Appreciating such biases is essential in comparisons of data between different sites.

More popular has been the use of internal standards. One approach is to present data as ratios of resonance intensities relative to a signal that is assumed to be relatively invariant, e.g. use of the creatine signal as an internal reference in proton MRS, or ATP in phosphorus MRS.^{31,66} This method assumes that relative relaxation rates are unchanged in the pathological volumes and that concentrations of the chosen reference signal do not vary between normal-appearing and pathological tissue (note the results in Figure 3). When comparing metabolite signal intensity ratios from different regions of the brain it is necessary to be aware of the regional variation in relative signal intensities in the normal brain or to compare only identically localized volumes (Figure 2).³²

The validity of assumptions of invariance of internal reference signals can be tested by comparisons of absolute signal intensities with anatomically homologous volumes in the (unaffected) contralateral hemisphere. Care should be taken even with this control, however, as pathology in one hemisphere may have secondary physiological, biochemical, or anatomic effects in the contralateral hemisphere because of the extensive connectivity of the two hemispheres. With this concern in mind, absolute signal intensities can also be compared directly between lesions and normal-appearing contralateral hemispheres. While this is probably valid in some situations, it will not be in others. For example, it may be true for creatine in chronic multiple sclerosis,^{30,31,42} but certainly does not hold true for brain tumors.^{3,12}

2.4 Statistical Analysis of Spectroscopic Data

Single voxel methods produce a single spectrum, which simplifies the problem of data quantitation and comparisons. The data are biased by subjectivity in the volume selection, but are potentially statistically powerful.

Spectroscopic image data sets are much more difficult to analyze. Comparisons based on the subjective choice of only certain voxels within the MRS image introduces bias, as in the case of single voxel examinations. Use of more than one voxel to characterize a focal lesion is complicated because the voxels are not statistically independent measurements. An appropriate correction for their spatial correlations must be made.⁶⁷ Finally, comparisons with normal data that also consist of image data sets is complex. Objective comparisons of groups of spectroscopic images and statistical analysis of the significance of differences requires the development of a new statistical methodology that avoids sampling bias, is efficient despite a low

signal-to-noise ratio, and takes into account the spatial variation and correlations in the images. However, such procedures have been developed for other applications, such as the analysis of satellite photographs.⁶⁸

3 CONCLUSIONS

Preliminary results have demonstrated that brain MRS may be able to provide potentially important information concerning localized changes in brain chemistry associated with focal pathologies. Because focal pathologies are often the object of active treatments (e.g. for abscesses or tumors) or efforts to develop effective treatments (e.g. for stroke or multiple sclerosis), this type of pathology may provide a major justification for integration of MRS into clinical neurological and neurosurgical practice. However, at the time of writing, several fundamental problems still limit the practical availability of reproducible, quantitative spectroscopic data.

The intrinsic limitations on the signal-to-noise ratio in MRS and relaxation properties of the nuclei of interest limit spectroscopic resolution relative to water-based proton images. Despite the desirability of further increases in resolution, a practical balance is necessary between resolution and the time required for acquisition in clinical studies.

Comparisons of spectroscopic image data between individuals, individuals and groups, and between serial examinations of an individual are fundamental to clinical applications. However, they are difficult to perform rigorously. Accurate preplanned registration is likely to remain essential for spectroscopic data acquisition. Techniques that allow registration to a standard anatomical space can provide averaged normative data with a much improved signal-to-noise ratio relative to individual studies for more accurate quantitative assessment of data from pathology in an individual subject.

Application of spatial statistics⁶⁸ should facilitate efficient, unbiased assessment of spectroscopic image data. Statistical approaches such as this potentially allow meaningful comparison of data obtained from a variety of modalities. Of particular interest also is the potential for simultaneous assessment of structural and biochemical MR data.

1 INTRODUCTION

In 1973 Moon and Richards¹ described a noninvasive approach for the determination of conditions within cells, such as pH, by observing the magnetic resonance signal of ³¹P from intracellular phosphates whose chemical shifts vary significantly with pH (see Figure 1). In this study of the pH within erythrocytes they monitored the chemical shift of the two ³¹P signals of intracellular 2,3-diphosphoglycerate and found that the intraerythrocytic pH of whole blood was the same as that of packed cells, as well as that of hemolysates of packed red blood cells. This and analogous approaches have since been used to study a wide variety of biological systems including ion transport in plants,² the metabolism of flight in insects,³ as well as human physiology and pathology, the particular focus of this discussion.

To determine the pH of biological samples by NMR spectroscopy the presence is required of a molecule containing a nucleus with appropriate magnetic properties. The chemical shift of the nucleus in the molecule should vary significantly with pH and the molecule should have a pK_a close to that of the environment whose pH is being determined. The ³¹P nucleus satisfies these conditions. Its spin quantum number of $\frac{1}{2}$ provides high-resolution spectra; its 100% natural abundance and inherent sensitivity give an observational sensitivity of 6.6% relative to ¹H; molecules that contain ³¹P are often present in biological samples at millimolar (mM) concentrations. These factors allow the collection of one-dimensional spectra within short periods of time to determine ³¹P chemical shifts. Inorganic phosphate can serve as a pH-sensitive indicator as the pK_a for dihydrogen phosphate is near 7 and the two differently protonated forms are in rapid exchange ($k \sim 10^9\text{--}10^{10} \text{ s}^{-1}$).

The chemical shifts of monohydrogen phosphate and dihydrogen phosphate differ by about 2.35 ppm. On a 500 MHz instrument (where ³¹P nuclei resonate around 202 MHz) this corresponds to a frequency difference between the two differently protonated forms of 475 Hz, which is well below the chemical exchange rate of $10^9\text{--}10^{10} \text{ s}^{-1}$. In such situations one observes a single resonance for the two forms; the chemical shift represents an average weighted by the relative concen-

trations of the two forms. Since most biological systems normally have pH values near 7, the changing relative concentrations of these two forms with varying pH leads to a ³¹P signal that sensitively reflects the pH of the environment.

Since features of the environment, other than pH, can also influence the chemical shifts of ³¹P nuclei, one requires a reference signal whose chemical shift should ideally be independent of pH. For many systems phosphocreatine serves this function; it is completely ionized near physiological pH:

and has a chemical shift 3.5–5.5 ppm away from that of inorganic phosphate in the range of physiological pH. Thus by constructing reference titration curves under conditions that simulate those of the biological sample (as shown in Figure 2) one can determine the pH of the biological system itself. In situations where no phosphocreatine signal is present, as in liver, the α-phosphate of ATP can serve as a reference, though one must recognize that its chemical shift changes with pH as shown in Figure 1. Other internal references, such as cell water⁴ or an external reference, such as a vial of methylene diphosphonate, can also be used.

Nuclei other than ³¹P can also serve as probes. For example esterified F-quene-1,⁵ can enter a cell where the ester groups are then hydrolyzed. The resulting F-quene-1 cannot cross the cell membrane and becomes trapped intracellularly. The ¹⁹F signal of F-quene-1 has been used to monitor the intracellular pH of rat liver, for example. The ¹H signal from C-4 of histidine in the hemoglobin of erythrocytes⁶ and of anserine in muscle,⁷ as well as the ¹³C signal from C-3 of *sn*-glycerol 3-phosphate, have also been used as probes to determine pH.

Figure 1 The pH-dependent chemical shift behavior of a variety of biological organic phosphates. Chemical shifts are reported relative to external 1.0 M phosphoric acid. F6P, fructose 6-phosphate; DPG, 2,3-diphosphoglycerate; CP, carbamyl phosphate; Pi, inorganic phosphate; ATP, adenosine triphosphate. (Reproduced by permission from R. B. Moon and J. H. Richards¹)

Figure 2 Variation of the chemical shift of inorganic phosphate with solution pH. The chemical shift is expressed relative to two different standards: methylene diphosphonate (MDP) and phosphocreatine (PCr) at pH 7. Solutions containing 10 mM inorganic phosphate and 10 mM phosphocreatine were adjusted to various ionic strengths by addition of KCl or NaCl and titrated at 37°C by addition of HCl and KOH or NaOH. Symbols: ◆ 120 mM KCl; ● 160 mM KCl; ■ 200 mM KCl; ★ 160 mM NaCl. (Reproduced by permission of Clarendon Press, from D. G. Gadian, 'Nuclear Magnetic Resonance and its Applications to Living Systems', 1982, p. 32)

The introduction of wide-bore magnets and whole body spectrometers that operate at fields from 1.5 to 7 T, permit observations of perfused organs, whole animals, and humans. Surface coils⁸ or localization protocols such as image-selected in vivo spectroscopy⁹ and chemical shift imaging^{9,10} pulse sequences have become popular methods for acquiring a ³¹P signal from a specific volume element of the subject. Such instruments and techniques can give important information from liver, kidneys, muscle, and brain, as well as cell cultures and ex vivo tissue samples.

2 RELIABILITY

The inherent precision of MRS measurements of pH in favorable circumstances is around 0.06 pH units.¹¹ In real biological samples, additional sources of error arise due to partial volume effects caused by the signal from the region of interest being compromised by signal from other regions of the sample. For example, the ³¹P spectra of in vivo liver often contain a phosphocreatine peak whose source is the surrounding muscle. Even for a signal from a homogenous tissue or cell population, the same substance in various compartments can complicate the interpretation by giving rise to more than one signal. For example, studies on various tumors¹² reveal that the signal for inorganic phosphate originates from about 65% intracellular phosphate and 35% phosphate in the extracellular space. Accordingly, an observation of inorganic phosphate in tumors reports a pH that is somewhat weighted toward the intracellular pH despite the fact that the extracellular volume of a tumor sample exceeds that of normal tissue.

Mitochondrial preparations show two signals for inorganic phosphate, one within the mitochondria, the other from the medium.¹¹ The different pH values arise because of pH gradients across the membranes that separate the compartments; in the cases discussed, the magnitude of the pH differences accord

with Mitchell's chemosmotic hypothesis.¹³ Signals can also arise from different intracellular compartments as in aerobic preparations of rat liver; one signal represents cytoplasmic phosphate, the other comes from phosphate within the mitochondria that are so abundant in such samples.

3 CANCER

One of the earlier and significant contributions of MRS pH measurements concerned the intracellular pH of tumors, which was found to be from neutral to alkaline,^{12,14–16} in direct contrast with the standard belief of the day that tumors were acidic.^{17,18} Tumors produce excess lactic acid (because of appreciable anaerobic metabolism) suggesting an acidic intracellular pH, a surmise which studies with microelectrodes supported.¹⁸ Thus MRS results gave a pH in the 6.9–7.4 range, whereas microelectrodes reported pH values in the 5.6–7.6 range. In fact, tumor cells do contain unusually high amounts of anionic lactate¹⁹ (not lactic acid as was once assumed) because they probably export the protons which then accumulate in the extracellular regions in unusually large amounts because of the incomplete equilibration that results from the compromised blood circulation in many solid tumors. In these circumstances microelectrodes report more the extracellular acidic pH than the neutral intracellular pH that MRS allows one to observe noninvasively. This result has proved significant in rational design of anticancer drugs.

4 MUSCLE

Moderate exercise of muscle leads to intracellular acidosis. Indeed the pH can drop from 7.1 to values as low as 6.0.²⁰ After stopping exercise, the pH recovers to normal values within 1 min. Some protocols for moderate exercise show little or no decrease in intracellular pH.²¹ As one would expect, more vigorous exercise, or exercise under ischemic conditions, causes a more profound intramuscular acidosis,²² as shown in Figure 3. Interestingly, and reassuringly for athletes and fitness fans, similar levels of exercise after training cause significantly less acidification than that for untrained individuals and this benefit extends even to those muscles not specifically trained.²⁰ Exercise protocols can also be used to study the pathology of various muscle diseases. For example, patients with myotonic dystrophy show a smaller decrease in intramuscular pH with exercise, and their muscles also return more rapidly to a normal value than do those of controls.²³ Furthermore, patients who lack glycogen phosphorylase (McArdles syndrome) actually manifest the expected increase in intramuscular pH due to the unmasking of the alkalinizing hydrolysis of phosphocreatine to phosphate and creatine.

5 HEART

To monitor transient ischemia, the effects on heart muscle of occlusion of the coronary artery followed by reperfusion have been monitored by ³¹P MRS. In a perfused heart ligation, occlusion of the left anterior descending artery^{24,25} caused a decrease in pH from 7 to 6.7. In a globally ischemic heart, the

Figure 3 Phosphorus-31 NMR spectra in a control subject showing the effects of (a) normal aerobic exercise and (b) ischemic exercise. A 1.9 T, 20 cm bore magnet and a 4.5 cm surface coil were used to acquire signal from about 25 mL of the subject's flexor compartment of the forearm. Phosphorus-31 spectra were recorded at 32.5 MHz with an interpulse delay of 2 s, sweep width 4 kHz, and a line broadening of 6 Hz used before Fourier transformation. The exercise protocol involved flexion of fingers at 2 s intervals. The signals are assigned as follows: 1, 2, and 3, the β , α , and γ phosphates of ATP; 4, phosphocreatine; and 5, inorganic phosphate. The pH value given above each inorganic phosphate signal was determined from the frequency separation of the inorganic phosphate and phosphocreatine signals. (a) Zero minutes corresponds to the start of exercise and was maintained for 5 min. Spectra A and E were accumulated with 64 scans; the other spectra were accumulated with 32 scans. The pH value is an average in spectra where the inorganic phosphate signal is split into two components. (b) Zero minutes corresponds to the start of exercise and was maintained for 1.5 min. Arterial occlusion was maintained from zero minutes to 3 min with arterial flow being restored after this period. (Reproduced by permission from B. D. Ross, G. K. Radda, D. G. Gadian, G. Rocker, M. Esiri, and J. Falconer-Smith, *N. Engl. J. Med.*, 1981, **304**, 1338)

pH falls to 6.2.^{26,27} In dogs, occlusion of the left descending coronary artery caused the pH to decrease to 5.9; in some cases the pH recovered spontaneously to preocclusion values presumably because of the development of collateral flow to the affected myocardium.²⁸ Other hearts showed more permanent changes reflecting a decreased pH that was consistent with the ischemia. These pH changes occurred within minutes of the occlusion.

One can even observe the results of exercise-induced ischemia in the human heart in vivo, despite the large ^{31}P signal from the 2,3-diphosphoglycerate in the red cells of the blood within the ventricles. Heart muscle cells have a relatively high density of mitochondria (30%) such that one might actually be able to observe the pH gradient between

the mitochondria and the cytosol. Such differences have been demonstrated in other tissues, for example lineshape analysis of ^{31}P spectra leads to a pH gradient of 0.5 in skeletal muscle^{29,30} and kidney.³¹ In the perfused rat heart, deoxyglucose, which is unable to enter mitochondria, and upon phosphorylation becomes trapped in the cytoplasm, gives the same pH value as that determined by using inorganic phosphate.³² This study suggested that the pH observed in heart muscle reflects that in the cytoplasm, possibly because intra-mitochondrial inorganic phosphate cannot be observed with present-day technology due to its low concentration and/or due to a broadened signal. Alternatively, the pH gradient may be small in heart muscle.

Calculations have shown that a pH difference of 0.3–0.4 is necessary to resolve the peaks for inorganic phosphate within or outside a cell when 65% of the observed MRS signal represents intracellular phosphate.³³ Nonetheless, separate MRS signals for Walker's tumors were unobservable even though the ΔpH was 0.6, as calculated from the distribution of lactate across the cell membrane; this failure was attributed to the poor signal-to-noise characteristic of this type of tumor.

6 BRAIN

Studies in the brain of animal models also show a similar decrease in pH due to ischemia. Unfortunately, correlation of these findings with other parameters such as preischemic glucose levels or the exogenous introduction of base to alleviate trauma, have provided inconclusive, and even in some cases contradictory, results.^{34,35}

7 FUTURE

Difficulties occasioned by low signal-to-noise or poor resolution hamper many studies now being undertaken with in vivo MRS studies of human pathologies. The introduction of whole body spectrometers with higher fields, the use of alternative nuclei such as ^{15}N (spectra of which can now^{36,37} be acquired in vivo), the ability to obtain high-resolution data from smaller, well-defined volume elements, the use of other endogenous metabolites or the introduction of exogenous reporting substances, provide hopeful new avenues to achieve noninvasively more reliable information about the metabolic status of organs, tissues, and other biological samples. The resulting insights will greatly broaden our understanding of the complex integrated metabolism of intact living systems. For humans, these advances can significantly enhance the power of diagnosis.

Phosphorus-31 Magnetization Transfer Studies In Vivo

Ruth M. Dixon

Department of Biochemistry, University of Oxford, Oxford, UK

1 BACKGROUND AND THEORY

The rates of certain chemical reactions can be studied by magnetization transfer techniques, the theory of which was first developed by Forsén and Hoffman.¹ The theory and uses of these techniques for measuring enzyme-catalyzed reaction rates are reviewed extensively elsewhere.^{2–6} This article will therefore give only a brief outline of the theoretical background, concentrating on the applications of the methods in living animals, and will include the small number of studies in human subjects.

1.1 Techniques

Perturbation of the magnetization of a species in chemical exchange with others causes a change in the magnetization of the other species that depends in general not only on the exchange rate constants k_{forward} and k_{reverse} , but also on the spin-lattice relaxation times (T_1) of the exchanging species. For a reaction involving two species, $A \leftrightarrow B$, the unidirectional fluxes through the reaction are $k_{\text{forward}}[A]$ for the forward reaction and $k_{\text{reverse}}[B]$ for the reverse reaction. The measured rate constants (k) are always first-order, or pseudo first order, that is, for reactions involving several substrates, the apparent rate constant is a function of the concentrations of the other metabolites. Two main types of experiment may be performed to measure the forward and reverse rate constants. In the first, a continuous radiofrequency irradiation selectively saturates one of the exchanging species and the changes in the other species are observed, either as a function of the time of irradiation, or at steady state. This experiment is known as saturation transfer (ST). In the second type of experiment [inversion transfer (IT)], a selective inversion pulse is applied to one of the exchanging resonances, and the temporal changes of all of the resonances are observed. In both experiments the various recovery curves of the exchanging species are fitted to suitable solutions of the Bloch equations modified for chemical exchange.^{1–6} For instance, in a steady-state ST experiment where species B is irradiated and species A is measured, the rate constant is given by:

$$k_{A \rightarrow B} = \frac{1}{T_1} \left[\frac{M_0}{M_s} - 1 \right]$$

where T_1 is the longitudinal relaxation time of A in the absence of chemical exchange, M_s is the signal from A in the

presence of a saturating pulse on B, and M_0 is the signal from A in the presence of a saturating pulse an equal distance on the opposite side of A. In this type of experiment, a separate determination of T_1 (with irradiation of the exchanging species) is required. (See also *Selective Excitation in MRI and MR Spectroscopy*).

Two-dimensional (2D) techniques (analogous to NOESY experiments) give cross peaks between resonances that are in chemical exchange. The rate constants can be derived from the dependence of the cross-peak volumes on the mixing time. Selective pulses are not required, but a separate 2D experiment is required for each delay time. Two-dimensional experiments have been implemented in vivo (reviewed in Kuchel⁶) but there have been few applications in whole organisms because of time constraints.

The range of exchange rates that can be measured by magnetization transfer techniques is limited by the chemical shift difference of the exchanging species (in Hz), and by the T_1 times. For exchange rates that are fast compared with the chemical shift difference, only one resonance at an average chemical shift is observed, while for very slow reactions, where $k \ll 1/T_1$, relaxation will occur before significant exchange has taken place. Therefore rate constants of the same order of magnitude as $1/T_1$ are optimal for measurement by magnetization transfer.

1.2 Reactions Studied In Vivo

The reaction most widely studied in vivo is the reaction catalyzed by creatine kinase (CK):

The phosphate of phosphocreatine (PCr) exchanges with the γ -phosphate of adenosine 5'-triphosphate (ATP γ -P). The role of CK is not fully understood, but various possibilities have been discussed (reviewed in Wallimann et al.⁷ and by Saks et al.⁸). It may simply buffer the free ATP and adenosine diphosphate (ADP) levels during periods of energy utilization, or PCr may act particularly in muscle as a transporter for 'high-energy' phosphate groups, by diffusing from the mitochondria to the myofibrils. Since PCr and Cr have higher diffusion coefficients in vivo than ATP and ADP, and Cr concentration is much higher than that of ADP, they may facilitate the exchange between the energy-producing and energy-utilizing sites in the cell. The calculation of free ADP concentration from the NMR-measured PCr/ATP ratio, the proton concentration, and the CK equilibrium constant, assumes that the reaction is at equilibrium in each tissue of interest. Magnetization transfer measurements have been used to confirm whether this is indeed the case, using the principle that if the flux through CK is much faster than the net utilization (or production) of ATP by the cell, the enzyme may be considered to be at equilibrium. The interpretation of these studies is, however, not always straightforward, and it is suggested that not all of the Cr flux is visible to NMR as a consequence of compartmentalization and immobilization of enzymes and substrates.⁹

Other enzymatic reactions that have been studied by magnetization transfer methods in vivo are those involving ATP exchange, for instance, inorganic phosphate (Pi) $\rightarrow$ ATP γ -P exchange, catalyzed by the mitochondrial F_1F_0 ATPase, glyceraldehyde-3-phosphate dehydrogenase, and phosphoglycerate

kinase, and ATP γ -P $\rightarrow$ Pi exchange, catalyzed by various ATPases. The exchange between ADP and ATP β -phosphates is also catalyzed by many enzymes, and so an apparent exchange is often seen between ATP γ -P and ATP β -P, which is in fact due to the saturation of ADP β -P, at less than 1 ppm upfield of ATP γ -P. As yet unexplained is the apparent exchange between ATP γ -P and ATP α -P that has been seen in some systems.

A rather different set of studies, that may also be termed magnetization transfer, involves the irradiation of the broad resonance that underlies the spectra from brain, liver, and some other tissues. These are discussed in Section 4.

2 WHOLE ANIMAL STUDIES

Most ^{31}P magnetization transfer studies in vivo have involved the CK reaction in skeletal muscle, heart, and brain. Extensive investigations of isolated systems such as perfused organs, immobilized cells, and tissue slices, have also been undertaken,^{2-5,10} but these are beyond the scope of this article (see also *Cells and Cell Systems MRS*).

2.1 Skeletal Muscle

Creatine kinase is found in the skeletal muscle of all mammalian species. During exercise, ATP is hydrolyzed to ADP, and this is rephosphorylated to ATP by CK. This process is so rapid that the level of ATP generally remains constant even during severe exercise, until the PCr level falls to zero. In vitro, the rate of ATP production from PCr increases as the ADP concentration is increased, suggesting that the reaction is substrate-controlled. In studies of intact rat skeletal muscle in vivo, however, no such increase with workload and calculated [ADP] was observed.¹¹ Indeed in one study, the flux from PCr to ATP was significantly lowered as the workload increased, despite a calculated ninefold increase in [ADP], which would be expected to result in a 70% increase in flux.¹² The CK reaction does not appear to be obligatory for muscle metabolism, in that rats fed with an analog of creatine, β -guanidinopropionic acid (β -GPA), have a 12-fold lower flux through CK (PCr $\rightarrow$ ATP) and 10% of the normal PCr concentration, but normal physiological performance under electrical stimulation.¹³ It was suggested that the results supported a role for CK in preventing sudden large changes in [ADP] (which may regulate oxidative ATP synthesis), but a role for PCr in facilitating diffusion of high-energy phosphates was not ruled out, since adaptive changes in muscle fiber type or blood flow could have occurred over the 6–10 weeks of β -GPA feeding. A more direct manipulation of CK activity was achieved by Brosnan et al.,¹⁴ who expressed the B isozyme of CK (normally found only in brain and heart) in the skeletal muscle of transgenic mice. The normal levels of the M isozyme were also expressed, resulting in a 49% increase in total CK activity in vitro. No changes in metabolite levels were found (confirming that the reaction is at equilibrium in normal and transgenic mice) but the ATP $\rightarrow$ PCr flux (measured by saturation transfer) doubled. It is possible that this reflects the lower Michaelis constant (K_m) for ADP of the B isozyme, although earlier

studies did not show a simple relationship between [ADP] and k .^{11,12} Transgenic mice lacking the M isozyme of CK were produced by van Deursen et al.¹⁵ These mice had only mitochondrial CK activity in their muscles, and normal levels of PCr and ATP, but no detectable flux through CK, measured by IT. Surprisingly, the PCr level fell during exercise and recovered with a similar timecourse to the controls, but this could have been catalyzed by the small amount of the mitochondrial isozyme, without the flux being detectable in the IT experiment. Studies of CK kinetics in transgenic mice have been reviewed by Nicolay et al.¹⁶

During steady state exercise and at rest, the ratio of the forward to reverse fluxes of CK should be equal, since the metabolite concentrations are constant. This was found to be the case in a study of resting rat muscle, obtained by saturation transfer.¹⁷ In a study of rabbit muscle¹⁸ the forward and reverse fluxes were equal when measured by fitting the initial recovery rates of an inversion transfer experiment, and the forward flux (PCr $\rightarrow$ ATP) determined by saturation transfer agreed well with the inversion recovery rates, but the reverse flux determined by saturation transfer was significantly lower. Although competing ATPase reactions would be able to account for this discrepancy, no ATP γ -P to Pi exchange was observed. It has been suggested that compartmentation of intracellular ATP may account for this type of discrepancy.¹⁹ A 2D study of rat muscle found no significant differences between the forward and reverse fluxes, and no exchange between ATP γ -P and Pi, ATP α -P, or ATP β -P,²⁰ in contrast to the saturation transfer studies.^{11,12} The differences arise from the fact that the 2D technique, like the IT experiment, follows the transfer of a transient pulse of magnetization, and would not detect small pools of exchanging metabolites that would be detected in the ST experiment, in which the pool is continuously labeled. A saturation transfer study of tetanically stimulated rat muscle showed that ATP turnover (Pi $\rightarrow$ ATP flux) showed an approximately linear dependence on calculated free [ADP], up to approximately an ADP concentration of about 90 μM .²¹ There are difficulties with measuring the ATP β -P to ADP β -P flux, as shown by Le Rumeur et al.²² They found that the overall rate of β -phosphoryl conversion increased with exercise in rat muscle but did not reach the expected rate, which should equal or exceed that of the reverse CK reaction, ATP $\rightarrow$ PCr (since this reaction includes β -phosphoryl conversion). The authors suggest that the flux is underestimated either because of compartmentation of ATP or because of imperfect saturation of ATP β -P (if its signal is broadened by binding to intracellular proteins).

Since PCr takes part only in the reaction catalyzed by CK, the forward flux (PCr $\rightarrow$ ATP) can be measured accurately by saturation of ATP γ -P. An image of the intensity ratio of PCr with and without irradiation of ATP γ -P therefore reflects localized CK activity. Such an image was produced by Hsieh and Balaban,²³ who showed that CK activity did not vary across the resting hind limb muscles of the rabbit.

2.2 Heart

The CK system has been investigated extensively in the heart, both in the isolated perfused heart and in vivo, in order to understand the metabolic coupling between oxidative phosphorylation and energy demand. Studies of perfused hearts led

to contradictory results concerning the relationship between the flux through CK and oxidative metabolism, and questions remain about the regulation in vivo.²⁴ Ingwall and co-workers showed that the pseudo-first-order rate constant (k) for myocardial PCr $\rightarrow$ ATP exchange in the open-chested rat correlated closely with the rate pressure product (a measure of cardiac function) whether this was depressed by hypoxia,²⁵ or increased by norepinephrine infusion.²⁶ The change in k was accompanied by significant changes in [PCr], [ATP], and calculated free [ADP]. It was concluded that the flux through CK is controlled by the availability of ATP during hypoxia, and by ADP levels during inotropic stimulation. In contrast, in the pig heart in vivo, a similar infusion of norepinephrine produced no significant increase in rate constant over a 2.5-fold increase in rate pressure product, nor any changes in [PCr] or [ATP] (and hence in calculated [ADP]).²⁷ Pacing the canine heart in vivo so as to double oxygen consumption, led to no changes in CK flux. The flux was estimated to be at least 10 times the flux through oxidative phosphorylation, confirming that the CK reaction is at equilibrium in this tissue.²⁸ The transmural variation of the CK reaction was studied recently in the open-chested dog heart by combining one-dimensional (1D) localization with saturation transfer measurements. A 61% increase in the PCr $\rightarrow$ ATP flux was observed from the endocardium to the epicardium, in the presence of constant ATP/PCr ratios. This difference could not be explained by differences in CK levels, oxygen consumption, or substrate levels, and led the authors to invoke possible differences in the rate constant of the reaction.²⁹ Discrepancies between the forward and reverse fluxes were found in the rat heart in situ, which could not be attributed to ATP $\rightarrow$ ADP or ATP $\rightarrow$ Pi exchange, but it was suggested that they could be due to a small pool of exchanging ATP in or near the mitochondria.^{3,30}

ATP synthesis rates were measured in the intact dog heart by measuring Pi $\rightarrow$ ATP flux before and after a period of ischemia, and an estimate of the contribution of the glycolytic enzymes glyceraldehyde 3-phosphate dehydrogenase and phosphoglycerate kinase to this exchange was made.³¹

An interesting use of saturation transfer (ST) to measure myocardial pH was demonstrated in sheep, dog, and cat hearts in vivo.³² The NMR signal from intracellular Pi in the heart is obscured by resonances from 2,3-diphosphoglycerate and Pi in the blood. ATP is in exchange with Pi in the heart, so difference spectra with and without saturation of ATP γ -P contained a resonance from myocardial Pi (a similar exchange in blood could not be demonstrated). The pH could be obtained from the chemical shift of Pi and was found to be about pH 7.0, that is, considerably lower than previous estimates (*pH Measurement In Vivo in Whole Body Systems*).

2.3 Brain

The brain also contains high levels of CK. The first study in vivo showed that the reaction is at equilibrium in the anesthetized rat brain, since the forward flux through CK (PCr $\rightarrow$ ATP) was about five times the steady state rate of ATP synthesis.³³ A lower reverse flux through CK was observed in this ST study, while a 2D study showed equal forward and reverse rates.²⁰ This problem was addressed by Degani et al.³⁴ in a study of the rabbit brain, in which IT data were compared with ST data from the same animals, and by Mora et al.³⁵ in the

monkey brain. The forward and reverse fluxes were equal, within experimental error, when IT data were analyzed, but the reverse flux was undetectably low in an ST experiment when the PCr resonance was irradiated. These results agree with other observations that ST experiments underestimate the ATP $\rightarrow$ PCr flux when inhomogeneous tissue is studied.⁴ Sauter and Rudin found that the CK forward flux (and k_{forward}) correlated linearly with the electroencephalogram intensity in rat brain when brain function was depressed or stimulated pharmacologically.³⁶

Mora et al.³⁷ also produced a map of CK activity in the monkey brain by combining a Hahn spin echo imaging sequence with selective saturation of ATP γ -P. The difference between this image and one obtained with control irradiation showed that CK activity was approximately uniform across the monkey brain in the sagittal plane, but since no slice selection was used, each voxel contained a mixture of white and grey matter. In the developing piglet brain, the CK rate constant and the forward flux were measured by ST localized by spectroscopic imaging and were found to be higher in white than in grey matter.

2.4 Other Organs

Magnetization transfer techniques have found few applications in other organs in the whole animal. Koretsky et al.³⁹ studied the rat kidney in vivo with chronically implanted radio-frequency coils. The Pi $\rightarrow$ ATP rate constant was estimated to be $0.12 \pm 0.03 \text{ s}^{-1}$, somewhat less than that obtained in the isolated perfused rat kidney ($0.35 \pm 0.05 \text{ s}^{-1}$). The CK reaction has also been studied in an implanted tumor in the hind limb of a rat.⁶

3 HUMAN STUDIES

Few studies have involved human subjects, and none, so far, have involved pathological conditions in patients. In skeletal muscle at 1.9 T, Rees et al.⁴⁰ found that the PCr $\rightarrow$ ATP flux was significantly reduced with exercise to 64% of the resting value of $8.5 \pm 0.7 \text{ mM} \cdot \text{s}^{-1}$ in 12 normal subjects. This decrease was similar to that found in rat muscle,^{11,12} but in contrast to the expected dependence of the flux on [ADP] and pH. More recently, Goudemant et al. found that if the exercise intensity was varied, the decrease in flux was found only at the highest workload.⁴¹ These authors argue that the results are not consistent with a 'shuttle' role for PCr in skeletal muscle, since this would lead to a functional coupling between energy production and the CK reaction, which was not, in fact, found. Instead, the role of the CK reaction is likely to be energy buffering. They suggest that the results could be explained by the formation at high workloads of a dead-end enzyme-Cr-ADP complex, stabilized by anions such as chloride and bicarbonate, as suggested by McFarland et al. from studies of cat muscle ex vivo.⁴² Walliman, however, argued that NMR may not accurately determine the total CK flux in muscle, and that these results are caused by varying degrees of compartmentalization during exercise.⁹

A 1D map of CK activity in brain was obtained by Cadoux-Hudson et al.⁴³ using phase-modulated rotating frame imaging combined with ST (see also *Rotating Frame Methods for Spectroscopic Localization*). Figure 1 shows a typical data set,

Figure 1 Stack plots of ^{31}P phase-modulated rotating frame images of human brain with (a) control irradiation; (b) irradiation of ATP $\gamma\text{-P}$; (c) the subtraction of (b) from (a). Repetition delay = 15 s, total number of transients for each data set = 80. (Reproduced by permission of FASEB from Cadoux-Hudson et al.⁴³)

Figure 2 (a) ^{31}P NMR spectra of human brain (entire axial section) with saturating irradiation applied at ± 2.7 ppm (arrows). Repetition delay (TR) = 1 s or 15 s. (b) Localized ^{31}P NMR spectra from 1-cm-thick sections through the anterior wall (lower) and septum (upper) of the heart in a resting volunteer with saturating irradiation applied at ± 2.7 ppm. (Reproduced by permission of Academic Press, from Bottomley and Hardy⁴⁴)

with control and on-resonance irradiation. The CK activity was significantly greater in regions of predominantly gray matter ($k = 0.30 \pm 0.04 \text{ s}^{-1}$, flux = $1.56 \pm 0.30 \text{ mmol}^{-1} \text{ L}^{-1} \text{ s}^{-1}$) than in white matter ($k = 0.16 \pm 0.02 \text{ s}^{-1}$, flux = $0.72 \pm 0.12 \text{ mmol}^{-1} \text{ L}^{-1} \text{ s}^{-1}$) in six normal subjects. In contrast, Bottomley and Hardy⁴⁴ found no significant variation of CK activity with brain region in an ST 2D chemical shift imaging (CSI) experiment in one subject at 4 T ($k = 0.42 \text{ s}^{-1}$, flux = $2.1 \text{ mmol}^{-1} \text{ kg wet weight}^{-1} \text{ s}^{-1}$). One-dimensional CSI with ST in the human heart resulted in a forward rate constant of 0.51 s^{-1} , and a flux of $5.6 \text{ mmol}^{-1} \text{ kg wet weight}^{-1} \text{ s}^{-1}$.⁴⁴ Figure 2 shows spectra from this study, with control and on-resonance irradiation of ATP $\gamma\text{-P}$ in heart and brain. The decrease in PCr with irradiation of ATP $\gamma\text{-P}$ can clearly be seen in both tissues.

The technique of functional MRI based changes dependent on blood oxygenation was recently used together with localized ^{31}P ST to measure the activation of the visual cortex during visual stimulation.⁴⁵ This study showed that the forward rate constant for PCr $\rightarrow$ ATP $\gamma\text{-P}$ increased significantly within the visual cortex from $0.56 \pm 0.19 \text{ s}^{-1}$ (control) to $0.76 \pm 0.29 \text{ s}^{-1}$ during visual stimulation, in the absence of any detectable change in PCr/ATP or PCr/Pi ratios.

4 BASELINE FLATTENING AND PHOSPHOLIPID BILAYERS

The ^{31}P NMR spectra of brain, liver, kidney, and breast all show a broad signal in the phosphodiester region that cannot wholly be accounted for by the water-soluble phosphodiesters glycerophosphorylcholine and glycerophosphorylethanolamine. A study of liver and brain slices in vitro, and of liver in vivo, showed that this resonance was characteristic of phospholipid bilayers broadened by shielding anisotropy.⁴⁶ Irradiation of the wings of the broad resonance, 28 ppm from its maximum, completely eliminated the broad resonance from rat liver spectra in vivo, allowing the remaining resonances to be quantified more accurately.

Proton Decoupling During In Vivo Whole Body Phosphorus MRS

Rolf M. J. N. Lamerichs and Peter R. Luyten

Philips Medical Systems, Best, The Netherlands

1 INTRODUCTION

In vivo MRS in humans started with the measurement of phosphorus spectra in muscle tissue (see also *Whole Body Studies: Impact of MRS*). These first measurements were directed toward the assessment of muscle metabolism by using surface coils to localize the spectral information to a confined region of interest. With the advent of localization techniques, in vivo whole body phosphorus spectroscopy could also be used to study metabolism in other regions of the human body. Localized brain spectra have been used to study the metabolic changes in intracranial tumors, stroke, epilepsy, and white matter disorders. Liver and heart phosphorus spectroscopy have provided metabolic information on stress and ischemic conditions.

In spite of mature localization techniques for spatially selective phosphorus spectroscopy, the clinical efficacy of these techniques is hampered by a number of physical limitations. First, phosphorus spectroscopy is an eternal struggle for a better signal-to-noise ratio. Volumes of interest smaller than 10 cm³ will usually result in excessive measurement times, excluding those techniques for relatively focal pathologies. Higher field strengths may overcome this fundamental problem to some extent. However, the linewidth of in vivo NMR signals is predominantly determined by tissue susceptibility, which results in broader lines at higher field strengths. This effect limits the advantages of increasing the field strengths. Another reason for poor ³¹P signal detection is the low intensity for some ³¹P resonances due to complex *J* coupling patterns with protons. Further complications may result from the overlap of resonance frequencies between different components.

One technique which may alleviate these limitations to some extent is the use of proton decoupling in combination with whole body ³¹P spectroscopy.¹ Proton decoupling may simplify the structure of the spectrum by suppressing the heteronuclear *J* modulation patterns due to coupling with the spin-spin protons. Moreover, excitation or saturation of the surrounding protons in the tissue may contribute to the signal strength of the individual phosphorus signals by virtue of the nuclear Overhauser effect (NOE).²

The use of double resonance techniques in whole body ³¹P MRS results in considerable signal enhancement which improves the clinical utility of ³¹P MRS.

2 DECOUPLING OF ³¹P SIGNALS

The limited chemical shift dispersion of in vivo ³¹P NMR spectra obtained at the relatively low field strengths used for human applications may be the cause of poor spectral resolution. Excellent shimming over the region of interest is an absolute necessity for good in vivo spectral resolution. Depending on the relevant tissue susceptibility and volume of interest size, a homogeneity of 0.05–0.3 ppm (full width at half maximum) can be achieved. Methods to accomplish this homogeneity either employ the spatially resolved water signal in an iterative shim process or generate *B*₀ maps obtained from phase-sensitive imaging methods. After shimming, the linewidth will be 1.5–7 Hz at 1.5 T for in vivo ³¹P NMR resonances. These linewidths are sufficient to resolve the homonuclear ³¹P *J* couplings of ±17 Hz between the three nuclear ³¹P spins of adenosine triphosphate (ATP). Since the three-bond isotropic heteronuclear coupling between protons and phosphorus is in the range of 6–10 Hz, this coupling may become the dominant factor in the residual resonance linewidth of ³¹P nuclei coupled to one or more protons, such as in 2,3-diphosphoglycerate (2,3-DPG), nicotinamide adenine dinucleotide (NAD⁺), phosphoethanolamine (PE), phosphocholine (PC), glycerophosphoethanolamine (GPE), glycerophosphocholine (GPC), and α-ATP. Therefore, proton decoupling at a field strength of 1.5 T combined with an excellent local homogeneity can improve spectral resolution substantially, resulting in more resolved resonances and more reliable, quantitative information. At higher field strengths proton decoupling of ³¹P MR signals will be less effective due to the increased linewidths, which may become larger than the actual *J* couplings.

3 THE NUCLEAR OVERHAUSER EFFECT AND ³¹P SIGNALS

Irradiation of protons during in vivo ³¹P spectroscopy results in signal increase due to collapse of multiplet structures into singlets. Furthermore, this irradiation may introduce NOE which also results in significant signal increase. This signal enhancement affects not only ³¹P nuclei that are coupled to protons within the same molecule, but also noncoupled resonances, e.g. the phosphocreatine (PCr) signal, may show a substantial increase in signal intensity during saturation of the surrounding water protons. Due to the heteronuclear dipolar relaxation mechanism and the long dipolar cross-relaxation times between the ³¹P and ¹H water nuclei, the NOE may be quite effective. After application in animal studies,³ different irradiation schemes have been suggested for whole body in vivo applications that result in enhancement of the ³¹P signal. These methods range from low-power single-frequency irradiation at the H₂O resonance, which proved to be quite effective in generating NOE in ³¹P spectra of calf muscle,⁴ to truncated driven or transient NOE techniques.⁵ These methods are relatively simple to implement on a whole body MR scanner equipped with a second rf channel. Like decoupling, the NOE may result in relatively larger signal enhancements at lower field strengths. This is related to the inherent relaxation mechanisms for the ³¹P nuclear spins. The two most important relaxation mechanisms for in vivo ³¹P signals originate either from dipolar interactions or from the shielding anisotropy. Because this

latter relaxation mechanism is proportional to B_0^2 , it becomes the predominant relaxation mechanism at higher field strengths, resulting in a decreased NOE.

4 EXPERIMENTAL IMPLEMENTATIONS

A variety of effective pulse sequences have been developed for decoupling purposes, especially for high-resolution NMR applications. A well-defined decoupling sequence requires a homogeneous decoupling field B_1 , whose magnitude exceeds the strength of the J couplings involved and covers the entire spectral range of the proton spectrum that has to be decoupled. Broadband decoupling techniques generally rely on repeated inversion of the proton spins. Therefore, they require inversion pulses with a repetition time that is short compared with $1/J$. For proton decoupling of in vivo ^{31}P NMR signals, these conditions are easily fulfilled with the current 1.5 T whole body technology.¹ First of all, the J couplings involved are very small, only of the order of 6–10 Hz. This allows for relatively long pulses, and concomitantly for low rf power levels to decouple sufficiently. Furthermore, the relevant in vivo proton resonances coupled to phosphorus nuclei resonate in a small chemical shift range of ± 100 Hz around the H_2O resonance. This again allows for low rf power without affecting the broadband decoupling performance.

Sufficient decoupling power can be generated utilizing a WALTZ-4 sequence using a basic 90° pulse length of $900\ \mu\text{s}$, corresponding to an expected decoupling bandwidth of ± 280 Hz around the water resonance. These values allow for the use of large resonators such as standard whole body ^1H transmission coils employed on clinical MR scanners. For NOE the conditions are even more favorable. As most NOE contributions are expected to originate from the tissue water only, a low-power single-frequency irradiation of the water protons can be sufficient to generate large NOE enhancements.

5 APPLICATIONS

As the availability of second rf channels on clinical 1.5 T scanners is limited, the number of in vivo applications is quite restricted. However, for all applications of ^{31}P MRS, especially for studies on focal pathologies, proton decoupling showed an important improvement in the sensitivity of the technique. An illustration of the effect of broadband proton decoupling is given in Figure 1. The lower part shows a coupled ^{31}P spectrum of the human calf. The upper part shows the effect of proton decoupling, which clearly demonstrates how the multiplets of GPC and NAD resolve into two singlets. Another example is given in Figure 2, showing the resolved PE, GPC, and GPE resonances in the localized ^{31}P spectrum of the brain of a 6-year-old girl. These particular resonances are important indicators for membrane metabolism. These mono- and diester signals are used for the assessment of tumor metabolism and therapy response. Increased resolution will greatly enhance the potential of localized ^{31}P MRS in several important applications.

Figure 3 shows the effect of proton decoupling on the localized ^{31}P spectrum in the normal human myocardium. The lower trace shows the spectrum without any data processing,

Figure 1 1.5 T ^{31}P NMR spectra of the human calf. The spectra were obtained for 64 transients and a repetition time of 3 s using a 14 cm diameter surface coil without spatial localization. (Reproduced by permission of Wiley from Luyten et al.¹)

whereas the middle spectrum is the result of a time domain fitting routine (see also *Quantitation in In Vivo MRS*). The upper trace represents the residual signal between raw and fitted data. The spectrum shows a resolved inorganic phosphate (Pi) signal. Without any proton decoupling this signal would

Figure 2 Proton decoupled ^{31}P NMR spectrum of the brain of a 6-year-old girl who has a history of chemotherapy for leukemia. The spectrum was acquired using a small ^{31}P NMR head coil, and a regular ^1H imaging head coil for decoupling. WALTZ-4 decoupling was applied; the spectrum was obtained for 256 transients, with a 3.5 s repetition time. Proton decoupling has helped to resolve resonances from GPC, GPE, PE, and NAD^+ . DPDE = diphosphodiester. (Reproduced by permission of Wiley from Luyten et al.¹)

Figure 3 Proton decoupled ^{31}P spectrum of the left ventricular myocardium of a healthy subject. The acquired spectrum (bottom), simulated spectrum (middle), and the difference between the acquired and simulated spectra (top) are illustrated. Indicated are the signals from 2,3-DPG, inorganic phosphate (Pi), GPC, phospholipid signal from the blood (BPL), PCr, and ATP. Three-dimensional localization was applied by combining one-dimensional phase encoding and two-dimensional image-selected in vivo spectroscopy column selection. (Reproduced by permission of the Society of Magnetic Resonance Imaging from de Roos et al.⁶)

Figure 4 Proton decoupling and NOE applied to the human calf. The spectra were obtained for eight transients with a repetition time of 3 s. Spectrum A was acquired without any ^1H irradiation, spectrum B with proton decoupling (WALTZ-4) during acquisition of the ^{31}P signal only, spectrum C with decoupling and an inversion pulse on the ^1H signal 1000 ms before ^{31}P data acquisition (transient NOE), and spectrum D by combining WALTZ-4 decoupling during ^{31}P data acquisition with continuous single-frequency low-power irradiation of the water resonance during the relaxation delay

have been obscured by the overlapping 2,3-DPG signal from blood. This resolution is absolutely required to determine the intracellular pH, which is 7.15 for this particular spectrum.

Figure 4 summarizes signal enhancements that can be expected from NOE and decoupling separately. Spectrum A was obtained without the use of any proton irradiation. Broadband decoupling during ^{31}P signal acquisition was applied to obtain spectrum B, whereas spectrum C was obtained by broadband decoupling combined with an inversion pulse on the water resonance to create a transient NOE. Continuous irradiation during the entire experiment results in the largest enhancement (spectrum D): continuous low-power (5 W) single-frequency irradiation of the water resonance during all relaxation delays and broadband proton decoupling during ^{31}P acquisition were used. The NOE factors for PCr in spectra B, C, and D are 0.35, 0.50, and 0.64, respectively. For purely ^{31}P - ^1H dipolar relaxation and under extreme narrowing conditions the maximum enhancement factor is given by $\eta = \gamma(^1\text{H})/2\gamma(^{31}\text{P}) = 1.24$. This implies that combined broadband decoupling during acquisition and single-frequency low-power irradiation at the water resonance frequency during all relaxation delays results in a substantial signal increase. This effect may have an important impact on the quantification of ^{31}P MR signals that are obtained using double resonance techniques.

6 SAFETY CONSIDERATIONS

Continuous irradiation or broadband decoupling during relatively long acquisition intervals may result in excessive sample heating. This phenomenon is well-known in high-resolution NMR, where sample cooling during the experiment is common practice. For in vivo experiments this requires extremely careful precautions to prevent tissue damage. Fortunately, proton decoupling of in vivo ^{31}P signals requires power levels which are on the safe side of the current US Food and Drug Administration safety limits for rf irradiation. The total power deposition required to obtain the result depicted in Figure 4, spectrum D, results in a continuous single-frequency power deposition of 5 W to obtain NOE enhancement, whereas the broadband decoupling consumed 150 W during the 512 ms acquisition interval. Using a TR of 3 s, this resulted in a worst-case average power absorption (under the assumption that all power is dissipated in the tissue, i.e. zero reflection and no cable losses) of 30 W. As these values relate to transmission with the body coil, total power absorption of this experiment is well within the safety guidelines. However, extreme precautions including a dedicated power delimiter for a second rf channel are still an absolute necessity for performing these experiments, especially when decoupling is performed with smaller (surface) coils, which may result in excessive tissue heating close to the conductors of the coil.

1 INTRODUCTION

High-resolution ^{13}C NMR spectroscopy has utilized the full 200 ppm range of the ^{13}C spectrum for exploring metabolism in cells.¹ The multiplet structure of the spectrum arising from heteronuclear J coupling to protons has been exploited for the assignment of resonances. The spin- $\frac{1}{2}$ ^{13}C isotope has only 1.1% natural abundance, but by using ^{13}C -enriched labeled substrates, metabolic pathways can be followed dynamically. In vivo human spectroscopy has so far mainly been limited to studies of triglycerides in adipose tissue and glycogen storage in liver and muscle because of the very low sensitivity of the ^{13}C signal compared with that from protons or ^{31}P . In order to increase the range of metabolites accessible to ^{13}C spectroscopy, or to improve the localization within the human body, every effort has to be made to improve the S/N. One route for improvement of the S/N is to exploit the heteronuclear coupling, either through manipulation of the population of the ^{13}C energy levels through the nuclear Overhauser effect (NOE) or polarization transfer, or by collapsing the multiplet lines through direct decoupling from the protons. The gated decoupling experiment imposes stringent technical demands. The proton and carbon channels need to be well isolated, and coil systems need to be designed with a large degree of decoupling of their mutual inductances, which are adapted to the relevant anatomy and capable of delivering the decoupling energies at the required volume of tissue. However the most stringent limit in experiment design arises from the near continuous rf irradiation at proton frequencies with the requirement that the local deposition of rf energy does not exceed the various national guidelines, and presents no risk to the human subjects.

2 THE EFFECT OF PROTON IRRADIATION ON THE ^{13}C SPECTRUM

Irradiation at proton frequencies can affect the ^{13}C spectrum in two ways. The first of these is enhancement of the ^{13}C sensitivity by using the heteronuclear coupling to alter the population of ^{13}C energy levels. This further divides into two techniques: NOE^{2,3} and polarization transfer. The NOE uses a continuous secondary rf (B_2) irradiation to saturate the proton levels of the coupled system, whilst cross relaxation transfers the high proton polarization to the ^{13}C levels leading to a new

steady state determined by the various relaxation processes. For purely dipolar relaxation the enhancement is $1 + \gamma_{\text{H}}/2\gamma_{\text{C}}$ or a factor of 3. Polarization transfer uses rf pulses applied to the protons to create population changes which are then transferred to the carbon levels. The SINEPT (SINE-dependent polarization transfer) sequence,⁴ for example, consists of two 90° pulses separated by a time determined by the coupling constant of the particular resonance to be enhanced and the proton transverse relaxation time. Although the enhancement is optimized for those multiplets exhibiting a particular J coupling, the enhancement available is $\gamma_{\text{H}}/\gamma_{\text{C}}$, or a factor of 4.

The second effect of proton irradiation on the ^{13}C spectrum is through coherent effects causing collapse of the multiplet lines. The idea is that if nuclear spins X, in our case the protons, of an AX coupled system are irradiated at a frequency centered on the chemical shift of X and at an intensity B_2 such that $\gamma B_2 \approx 2\pi J_{\text{AX}}$ then in the rotating frame the evolution of the A, or ^{13}C , magnetization vectors due to coupling is continually reversed and the multiplet line coalesces to a single peak. This is known as continuous wave (CW) decoupling.⁵ The effectiveness of the decoupling diminishes with offset of the proton frequency from the X resonance and B_2 intensity. Broadband decoupling attempts to apply decoupling equally for all metabolites in the ^{13}C spectrum. One method of doing this is to modulate the B_2 irradiation with a noise source.⁶ A second method uses composite pulses^{7,8} which are designed to give inversion over a wide range of frequencies. The most commonly used of the composite pulses is the WALTZ pulse⁹ consisting of the triplet $90^\circ(+X)180^\circ(-X)270^\circ(+X)$. Phase cycling of these pulses produces WALTZ-4, WALTZ-8, or WALTZ-16 with progressively less sensitivity to errors in rf phase shifts. For full decoupling the pulses need to be applied at a frequency greater than $2J$, where J is the largest coupling constant for the metabolites under consideration, and the average B_2 energy utilization is much greater than for CW decoupling.

Switching of the B_2 irradiation, or gated decoupling, depending on whether data are being acquired, can give any combination of sensitivity enhancement or multiplet collapsing since the timescales of the former are those of the relaxation processes whilst the coherent effects are instantaneous. Suitable gating of the B_2 irradiation throughout the duty cycle is therefore useful for minimizing the overall rf power deposition.

3 HARDWARE, COIL DESIGN, AND RF DEPOSITION

For a gated decoupling experiment a second transmit channel with frequency synthesizer, phase modulator, and power amplifier is required. Most workers have also specifically designed the system of coils needed for proton transmit and carbon transmit and receive. The coil design most widely used for human in vivo ^{13}C studies consists of a planar, circular, ^{13}C transmit-receive surface coil with a butterfly or figure-of-eight proton transmit coil, the crossover point being coaxial with the carbon coil center. This arrangement minimizes the inductive coupling of the two coils, and can be easily sited over the anatomy of interest with the long axis of the proton coil parallel to B_0 . Distributed capacitances are of course required to prevent electrical breakdown. In addition the proton transmit coil is gen-

erally spaced off from the subject to avoid regions of large B_2 field near to the coil. Further filtering is generally required to give the high level of magnetic isolation of the two frequencies so that the carbon receive signal is not degraded by the simultaneous proton frequency irradiation. For example Bottomley et al.,¹⁰ working at 1.5 T, using a 3-turn spiral 6.5 cm diameter ^{13}C coil and 8×13 cm air-cooled proton coil, achieved a 90 dB isolation of the 64 MHz signal at 16 MHz.

Rf power deposition in human NMR studies through the induction of eddy currents and Joule heating has long been a cause of concern and has led to guidelines limiting the specific absorption ratio (SAR) experienced by human subjects. In the USA the Food and Drug Administration (FDA) guidelines¹¹ are a body average SAR of 0.4 W kg^{-1} and a peak SAR of 8 W kg^{-1} in any 1 g of tissue, whilst in the UK the National Radiological Protection Board guidelines¹² are a body average SAR of 0.4 W kg^{-1} and a peak SAR of 4 W kg^{-1} in any 1 g of tissue. There is also a limit on the body temperature increase of 1°C . Bottomley and Roemer¹³ have used a homogeneous tissue model to investigate the power deposition for the coil arrangement described above and have compared their model with experimental observations of power deposition on the basis of the coil Q value using $P_{\text{absorbed}} = P_{\text{total}}(1 - Q_{\text{loaded}}/Q_{\text{unloaded}})$. They concluded that, although the theoretical homogeneous models probably overestimated the local power deposition in adipose tissue close to the coils, nevertheless, without care, the guidelines for peak SAR could easily be exceeded. Bottomley et al.¹⁰ in their studies on human limbs and chest using a noise-modulated decoupling source limited the decoupling power to below 8 W, which according to the above model limited the power deposited in tissue to 3 W. Using one-dimensional phase encoding methods in a phantom they estimated that some level of decoupling was sustained at depths of 6 cm whilst significant NOE was realized to depths of 4 cm.

Working at 4 T, Bomsdorf et al.¹⁴ used an 11 cm diameter carbon coil and a 7×14 cm butterfly proton coil, achieving 40 dB of isolation. It was concluded that broadband decoupling would not be possible at this field strength without exceeding the SAR limits, but studies on the calves of human volunteers were performed with gated CW decoupling. Decoupling power levels of 6 W were used for subcutaneous fat at a depth of 1 cm, and 24 W for muscle at a depth of 2.5 cm. Heating sensations for one volunteer at the higher power levels were eliminated by reducing the duty cycle, i.e. increasing the recovery period between data acquisitions. In addition, these workers, by careful positioning of the carbon surface coil, were able to use the body coil for proton transmit in polarization transfer experiments, where there is no proton irradiation during data collection. In this case for a repetition time of 200 ms the SAR was estimated to be $\sim 1 \text{ W kg}^{-1}$ and hence well within guidelines.

Saner et al.¹⁵ working at 1.5 T were able to use a 7 cm diameter carbon coil in combination with a standard head coil for CW decoupling, and were able to conduct polarization transfer studies without hardware modification. Applying the gated CW decoupling during a 64 ms data acquisition these authors estimated that the average SAR was 3.9 W kg^{-1} whilst the peak SAR was twice this, and thus just within FDA guidelines, but were able to demonstrate decoupling within calf muscle of a human leg.

Systems of concentric and coplanar circular coils have also been successfully used for decoupling. Beckmann et al.¹⁶ were able to use broadband decoupling at 1.5 T with circular coils of 8 cm (carbon) and 13 cm (proton) diameter. Using a WALTZ-8 sequence intercalated throughout the 70 ms data acquisition, and interspersing rest periods within the total data acquisition time to reduce the duty cycle, they estimated that the average SAR did not exceed 2.8 W kg^{-1} and also demonstrated decoupling within the calf muscle of a human volunteer. Finally, with this coil arrangement, gated CW decoupling through a 20 ms data acquisition and a 10% duty cycle, Avison et al.¹⁷ were able to demonstrate decoupling on a human calf muscle at 4.7 T.

4 HUMAN ^{13}C STUDIES

In whole body ^{13}C spectroscopy adipose tissue is the most accessible for study, especially if proton decoupling is required. Moonen et al.¹⁸ showed that all the resonances in the ^{13}C spectrum are due to triglycerides, and using the resonances of the olefinic signal from unsaturated carbons ($\text{C}^*=\text{C}^*$) at 129 ppm were able to determine the relative concentrations of poly- and monounsaturated fatty acids. This noninvasive technique has the additional advantage that adipose tissue from specific sites, e.g. waist or thigh, can be studied. This study was also performed on patients with cystic fibrosis.¹⁹ Beckmann et al.²⁰ by using long repetition times, were able to achieve sufficient S/N to quantify the relative concentrations of poly- and monounsaturated fatty acids in relation to dietary intake of fat without decoupling, but noted the poor resolution of the resonances at 130 ppm arising from long range couplings compared with the high resolution of the decoupled spectrum. Bryant et al.,²¹ using both coupled and decoupled spectra in a study of the adipose tissue of vegans and control subjects, demonstrated by this noninvasive technique a significant increase in unsaturated fatty acid content in the vegan subjects compared with controls. Ende and Bachert,²² using broadband decoupled ^{13}C spectroscopy of human calf and breast, sought to optimize the NOE enhancement, achieving maximum enhancements of 80%. With acquisition times of ~ 15 min they detected resonances other than those from triglycerides in breast tissue.

Glycogen in many ways has provided a test case for the implementation of human in vivo ^{13}C spectroscopy. It plays a central role in carbohydrate storage and metabolism in both muscle and liver, at depths of a few centimeters as far as NMR detection is concerned. Although fully NMR visible,²³ concentrations of around 84 mmol L^{-1} in muscle and up to 300 mmol L^{-1} in liver test the sensitivity of ^{13}C studies. The C-1 resonance of glycogen appears as a doublet at 95 and 106 ppm, but can be decoupled by CW decoupling, irradiating the proton spectrum at 5 ppm. In addition broadband decoupling is expected to give an S/N improvement of slightly more than 2 through the suppression of long range couplings. Short T_1 and T_2 values mean that the irradiation duty cycle times can be as short as 25 ms. Finally labeling studies can be easily and safely performed by the ingestion of ^{13}C -enriched glucose.

Decoupling and detection of the C-1 resonance of glycogen in human muscle and liver at 2.1 T was demonstrated by Jue et al. in 1987.²⁴ Using WALTZ-4 broadband decoupling at 1.5 T, Heerschap et al.²⁵ were able to follow the depletion and

recovery of glycogen in the gastrocnemius muscle of a fit volunteer following a 23 km run. They note that the broadband proton decoupling aids quantification both through narrowing the region covered by the high triglyceride signals and by allowing referencing against other metabolite signals, for example creatine, at 157 ppm. Depletion and repletion studies of glycogen in skeletal muscle following 2 h each of cycling and walking were recently performed²⁶ at 2.0 T without decoupling, with acquisition times to achieve quantifiable S/N of ~20 min.

A patient with glycogen storage disease has been studied by Beckmann et al.¹⁶ Muscle and liver spectra were obtained using WALTZ-8 proton decoupling. In calf muscle not only was an elevated C-1 glycogen resonance observed, but also resonances in the region 73–77 ppm, tentatively assigned to the C-4 and C-2,3,5 resonances of glycogen. For the spectra obtained from the abdominal region the authors note the problems of localization to the liver given the intense triglyceride signals for the overlying adipose tissue. The fact that the fatty acid content of the livers of normal western subjects tends to be high, together with the general broadening of liver signals, suggests that quantification will be difficult without decoupling. They were able to demonstrate the increased C-1 glycogen signal in the patient compared with controls, as well as resonances in the region 73–77 ppm. These authors also presented the first proton-decoupled ¹³C spectra from the human head, with a tentative assignment of a resonance at 54 ppm to creatine.

It should be noted that Saner et al.¹⁵ have compared the enhancement of the glycogen signal in human leg by CW decoupling with that of the much less rf intensive polarization transfer using the SINEPT technique, and concluded that, in vivo, both methods gave a gain of approximately 2.5. Work has also begun in gaining improved S/N from ¹³C signals by using labeling in conjunction with decoupling. Jue et al.²⁷ gave fasted volunteers a ¹³C-enriched glucose drink and obtained CW decoupled spectra using a surface coil placed over the right lobe of the liver. With a 15 min acquisition time they were able to obtain a baseline decoupled C-1 glycogen signal, and were then able to follow the increase in this resonance following ingestion of the glucose. They were also able to observe the α - and β -glucose resonances at 93 and 96 ppm.

Beckmann et al.²⁸ were able to compare glycogen formation in the human liver following ingestion or intravenous infusion of nonlabeled glucose as well as [1-¹³C]glucose with a low level of enrichment. Using WALTZ-8 decoupling the resonances of glycogen and α - and β -glucose were followed over time, showing greater glucose uptake by the oral route. Other labeling studies have also been performed. In a recent study²⁹ at 2.0 T, glutamine and glutamate in the human brain were observed in a ¹³C spectrum following infusion of [1-¹³C]glucose. Sensitivity and resolution were enhanced by the use of NOE and WALTZ-16 broadband decoupling, achieving line-widths of less than 2 Hz.

Other human in vivo ¹³C studies have been considered. For example, in 1988 Sillerud et al.³⁰ working at 1.5 T were able to observe the central resonance of the C-2,5 citrate triplet at 47 ppm in the human prostate, but were unable to resolve the outer pair of signals at 54 and 38 ppm. They noted that with narrowband decoupling and NOE enhancement a factor of 9 gain in S/N would theoretically be achieved, but to date no

decoupling studies have been attempted in this region. The trend has been rather to use improved technique and experience to move away from the technically demanding requirements of the gated decoupling experiment.

1 INTRODUCTION

The development of in vivo magnetic resonance spectroscopy (MRS) has provided a noninvasive means of chemically analyzing tissue volumes of a few cc's in the human body.¹⁻³ Ideally, diagnostic statements in the clinic should be based on numerical criteria derived from the measurement of absolute metabolite concentrations in normal and pathological tissue. Both the MRS measurement technique and the data analysis method may introduce substantial errors in obtaining absolute, or even relative, quantitative MRS data. For the introduction of MRS in the clinic as a standard method of diagnosis and of assessment of response to therapy, the development of a reliable user-unbiased quantitation methodology is therefore essential.

In this article, the quantitation of MRS data, rather than their acquisition, is discussed. The first step is to determine signal intensities. Ideally, the amplitude of an MRS signal of a metabolite, be it FID or echo, is proportional to the concentration of that metabolite. The method of choice for estimating the amplitude is to fit an appropriate model function to the data. This can be executed directly in the time (measurement) domain, or in the frequency domain after Fourier transformation (FT). Problem areas are, among others, low signal-to-noise ratio (S/N), coincidence of spectral frequencies, and magnetic field inhomogeneity. In the frequency domain, an additional concern may be estimation of the baseline. If no appropriate model function is available, one may either decompose the signal into a limited number of known well-behaved functions or apply integration in the frequency domain. Often the quality of quantitation can be increased dramatically by exploiting all available prior knowledge about experiment and signal. In addition, reference should be made to the fundamental limits of precision at the given S/N (Cramér–Rao bounds).

As a second step, the signal intensity ratios obtained may need corrections for the effects of relaxation, scalar coupling, several instrumental and pulse-sequence-dependent signal intensity distortions, and imperfect localization. Calibration of instrumentation and measurement methodology permits suitable

correction factors to be derived, and to obtain the prior knowledge mentioned above. Relative metabolite concentrations can be obtained in this way, and in principle also absolute ones, but at the cost of much greater effort.

There are a number of reviews of quantitative NMR.¹⁻¹¹

2 DATA ANALYSIS

2.1 Model Functions

The basic signal types encountered in in vivo MRS are FIDs and echoes. Since an echo can be looked upon as two FIDs back to back, most modeling aspects pertain to both types of signals.

A FID consists of a sum of damped sinusoids. Well-known functions for modeling the damping are $\exp(\alpha t)$, $\exp(\beta t^2)$, and $\exp(\alpha t + \beta t^2)$, in which α and β are negative. The frequency-domain counterparts of these functions have Lorentzian, Gaussian, and Voigt lineshapes, respectively. In practice, more complicated damping functions may be required—for instance when modeling an unresolved multiplet by a single sinusoid. In addition, the frequency of a sinusoid may be ill defined. The latter occurs when anisotropic interactions are not properly averaged out, or when the magnetic field is inhomogeneous.¹² For brevity, we consider only two cases:

1. the exponentially damped sinusoid and its frequency domain counterpart;
2. unknown functions and shapes.

The basic exponential function suitable for describing FIDs as well as echoes is

$$\hat{x}_n = \sum_{k=1}^K c_k e^{(\alpha_k^{\pm} + i\omega_k)t_n + i\varphi_k}, \quad n = 0, 1, \dots, N-1 \quad (1)$$

where c_k is the real-valued amplitude, $\alpha_k^{\pm}$ the damping factor, ω_k the angular frequency, and φ_k the phase of sinusoid k . All φ_k may be equal (an example of prior knowledge). The signal is sampled at times $t = t_n$.

If the signal is a FID, the time origin is set at the actual beginning of the precession. t_0 is the time of the first usable sample, relative to the origin just defined. In principle, t_0 can be inferred from experimental knowledge. In the absence of the latter, t_0 may be estimated along with the other unknown parameters.¹⁰

If the signal is an echo, the time origin is chosen such that at the echo maximum (t_{em}), $t = t_{\text{em}} = 0$. As for the damping factors, we have $\alpha_k^{\pm} \equiv \alpha_k^{+} > 0$ for $t < 0$, whereas $\alpha_k^{\pm} \equiv \alpha_k^{-} < 0$ for $t > 0$. Note that $|\alpha_k^{+}|$ and $|\alpha_k^{-}|$ need not be equal. $t_{\text{em}} - t_0$ may be known from the settings of the spectrometer. Alternatively, $t_{\text{em}} - t_0$ may be estimated along with the other unknown model parameters,¹³ as mentioned in the previous paragraph.

2.2 Estimation of Model Parameters

Quantitation amounts to estimation of the model parameters appearing in equation (1). Good results are usually obtained by

nonlinear least-squares (NLLS) fitting, which includes the variable projection method.¹⁴ If the noise is Gaussian, NLLS is identical to maximum likelihood estimation.¹⁰ An advantage of NLLS is that available prior knowledge about model parameters can be exploited, which yields significant reduction of the errors, especially at low S/N. A disadvantage is that good starting values of the parameters have to be provided in order to ensure correct convergence. Problems related to starting values and convergence can be avoided by resorting to simulated annealing¹⁵ or genetic algorithms,¹⁶ but these techniques require rather more computer time.

An alternative to maximum likelihood estimation is Bayesian estimation (BE),¹⁷ which requires prior probability distributions rather than starting values. One advantage of BE is that unwanted parameters (nuisance parameters) can be 'integrated out', and subsequently ignored. This may simplify the estimation process considerably. In addition, BE was successfully used for rendering maximum entropy (MEM) suitable for quantitation.¹⁸

Both NLLS and BE can be executed either directly in the time domain, or in the frequency domain following Fourier transformation (FT).^{17–24} In the time domain, the sample times t_n need not be uniformly distributed, which may be useful in multidimensional experiments, for example, for time saving.¹⁰ In addition, data truncation at either end does not affect the fit procedure. Frequency domain estimation is equally insensitive to data truncation if one obtains the model function from the discrete FT (DFT), rather than the usual continuous FT, of equation (1).^{8,21} When using the continuous FT, the resulting model function does not reflect data truncation, which in turn may necessitate judicious processing of the experimental baseline.^{25,26} Finally, we mention that in both domains, one can restrict the fit to only a small subset of the peaks (sinusoids), provided the frequencies in the subset differ sufficiently from those in the remainder.^{4,17,27} This property can yield substantial reduction of processing time. A new, very different, method capable of the same is that of *wavelets*.²⁸

If the residue of a properly converged fit clearly exhibits features above the noise, the wielded model function is evidently inadequate. In a number of cases, replacement of the Lorentzian model by the Gaussian or Voigt model may significantly improve the fit. However, notorious problem cases are the signals of, for example, water and fat, whose model functions are usually nondescript. The following two paragraphs indicate how one can still estimate the intensity of a nondescript signal, in both domains.

First, we consider the frequency domain, which is traditionally chosen for the task. If the baseline has been correctly estimated and the peak in question does not overlap with other peaks, the area of that peak is proportional to the amplitude of the related FID at the time origin. The FID amplitude, in turn, is proportional to the wanted number of molecules of interest. The gist of the method is that the peak area can be estimated by integration, without knowledge of the peak shape. Statistical and systematic errors attendant to the procedure have been treated by McLeod and Comisarov²⁹ and Nadjari and Grivet.³⁰ As with model fitting, one can restrict integration to just the peak(s) of interest. In cases where the model function is known, comparison of model fitting and integration has been done.³¹ Simulations showed that statistical errors of integration can be about equal to those of

Figure 1 ^1H MRS STEAM signals, echo time 20 ms, from the right parietal lobe of a human brain (experiment by P. Gilligan, J. MacEnri and J. T. Ennis, The Institute of Radiological Sciences, Dublin). The signal processing comprised (1) truncation of the data record at the beginning from 1024 to 1022 points and subsequently at the end from 1022 to 512 points; (2) removal of the residual water signal by subtracting exponentially decaying sinusoids, fitted by the HLSVD method;³² (3) quantitation in the time domain by the variable projection method,¹⁴ thereby multiplying initial data and model function by the same weighting function in order to account for a broad background feature.²⁷ The figure shows the cosine DFT of (a) the experimental signal after removal of the residual water signal; (b) the fitted model function; (c) the residue (a)–(b); (d) the original experimental signal

model fitting. Systematic integration errors, on the other hand, can be substantial.³¹

Recently, time domain quantitation of nondescript signals has been shown to be equally feasible.³² This is based on the fact that bell-shaped peaks of the kind encountered in spectroscopy can be represented in the time domain by a relatively small number of exponentially damped sinusoids. In agreement with intuition, the frequencies of the largest sinusoids are concentrated in the most intense region of the peak. Algorithms based on singular value decomposition (SVD) are available for the task.^{33,34} In NMR, such algorithms are known as LPSVD^{5–10} (linear prediction SVD), HSVD^{5–10} (Hankel SVD), HLSVD³² (Hankel–Lanczos SVD), HD³⁵ (Hankel diagonalization), EPLPSVD³⁶ (enhanced procedure LPSVD), and MV-HTLS³⁷ (minimum variance Hankel total least squares). The methodology is illustrated in Figure 1. Note that if the signal at hand is exponentially damped, SVD-based methods are viable alternatives to NLLS. An important advantage of these methods is that automation is easy. However, prior knowledge other than the number of sinusoids cannot be accommodated, and the S/N below which performance degradation begins (the threshold S/N) is higher than that of NLLS. However, a substantial reduction of the threshold S/N of SVD-based methods has recently been achieved.^{36,37} In addition, the considerable computational load of SVD is being lowered continually.^{32,38}

Table 1 Summary of Data Analysis Methods

	NLLS / BE	SVD-based	Integration
Model function	User-supplied	(see text)	—
Domain	Time/frequency	Time	Frequency
Prior knowledge	Accommodated	—	—
Starting values / distribution	User-supplied	—	—
Sampling interval	Arbitrary (time)	Uniform	Uniform
	Uniform (frequency)		
Truncation	Accommodated (time)	Accommodated	Baseline correction
	Baseline correction (frequency)		

Additional aspects such as robustness, computing efficiency, automation, and threshold S/N are difficult to quantitate, because they depend strongly on the particular implementation of the algorithm

2.3 Precision of the Model Parameters and Prior Knowledge

The standards against which one measures the precision of parameter estimates are the so-called Cramér–Rao bounds (CRBs).^{39,40} These are the smallest possible standard deviations under the given conditions. No estimator is capable of dodging the CRBs. The CRBs are derived from

1. the model function (including the ‘true’ values of the model parameters);
2. the noise level;
3. the sample times;
4. prior knowledge.

Prior knowledge may pertain to, for example, relations between model parameters of overlapping members of multiplets.^{13,41–43} Numerical studies of the CRBs reveal that prior knowledge is very beneficial for the precision of the remaining free model parameters. Other advantages of imposing prior knowledge are stabilization of the convergence process, lowering of the threshold S/N, and reduction of the computation time. Naturally, prior knowledge should be trustworthy.

Table 1 is a summary of data analysis techniques.

3 METABOLITE CONCENTRATIONS FROM SIGNAL INTENSITIES

3.1 Correction of Signal Intensities

Converting signal intensities to metabolite concentrations may need corrections for the effects of relaxation, scalar coupling, the applied pulse sequence, and instrumental parameters. The correction factors may be different for the separate lines.

3.1.1 Relaxation and Off-Resonance Effects

For repetition times T_r smaller than about four times the longitudinal relaxation time T_1 , the signal intensity of a line j in a FID-like experiment is affected by partial saturation, and depends on T_r , T_{1j} , the total dephasing time T_{2j}^* , the flip angle θ_j , and the offset frequency ω_j , in combination with the rf amplitude.⁴⁴ Corrections can be made because T_r , T_{1j} , T_{2j}^* , θ_j , and ω_j are known or can be determined. Partial saturation can be avoided, at the cost of the signal-to-noise ratio per unit time, by using large T_r values or small flip angles, if the in vivo experiment allows this. With inhomogeneous rf fields, the

flip angle depends on the position relative to the coil. In multi-pulse sequences, there is an effective flip angle depending on all applied pulses, and the signal intensity also has to be corrected for transverse relaxation during the delays. Experimental determination of T_2 values is easy for uncoupled but very difficult for strongly coupled spin systems. Metabolite T_{1j} and T_{2j} values may be age-dependent⁴⁵ and disease-dependent,⁴⁶ may show regional variations,^{47,48} and may change during the development of pathologies. If a reference compound is used to calibrate the instrument (see below), the T_1 and T_2 values of this compound should also be taken into account.

3.1.2 Radiofrequency Field Inhomogeneity

This causes flip angles and signal strengths to vary over the VOI, and degrades slice profiles. Surface coils are notorious in this respect. This spatially varying sensitivity can be corrected.^{11,49,50} The effects on the excitation of the spins can be minimized by using adiabatic rf pulses,⁵¹ but remain for the detection. Correction is (especially for surface coils) more essential for magnetic resonance spectroscopic imaging (MRSI) than for single voxel MRS, because the dimensions of the field of view for MRSI are in general larger than those of the VOI for MRS. Methods used to correct effects of B_0 inhomogeneity and eddy currents (see below) can easily be adapted to correct also for rf field inhomogeneity (see also *Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas*).

3.1.3 Static Field Inhomogeneity and Eddy Currents

These effects distort the resonance frequencies, intensities, phases, widths, and shapes of the lines over the VOI, complicating the data analysis and the calculation of spectroscopic images from the line intensities in each MRSI voxel. These distortions can be derived from a reference signal and used for corrections. An example is given in Figure 2. Based on this, several methods have been proposed in the literature^{12,52–54} and references cited therein.

3.1.4 Localization Effects

3.1.4.1 Radiofrequency field and B_0 inhomogeneity and eddy currents. For these, see Sections 3.1.2 and 3.1.3.

3.1.4.2 Slice and VOI Profiles. In single voxel MRS, slice and VOI profiles are not perfect, and depend on the rf inhomogeneity and pulse type, and the localization method. The

Figure 2 NAA spectroscopic image of a human brain, reconstructed from a 3D in vivo ^1H MRSI data set (experiment by R. M. N. J. Lamerichs, P. R. Luyten, and H. van Vroonhoven, Philips Medical Systems, Best). Important steps in the signal processing comprised (1) suppression of residual water signals and correction for phase and frequency variations over the pixels by postprocessing techniques; (2) quantitation by frequency domain integration or time domain NLLS fitting, in the latter case combined with exploiting prior knowledge of spectral parameters; (3) reconstruction of spectroscopic images from frequency domain peak areas (a) or time domain amplitudes (b). Note that lipid contamination is significantly reduced by the time-domain quantitation approach

signal from the intended VOI may become increasingly contaminated with signals from outside when the VOI becomes relatively smaller, especially in add-subtraction techniques such as ISIS,⁵⁵ where all spins within the sensitive region of the coil are excited. Single shot techniques for localization are therefore to be preferred. Moreover, the exact volume of the VOI is unknown, hampering the calculation of absolute concentrations. This requires exact calibration of the actual volume of the selected regions of interest.⁵⁶

In MRSI signal leaks from each voxel to the other voxels due to a discrete truncated sampling in k -space.⁵⁷ This results in severe contamination, especially when the sample contains discontinuities or sharp edges. In this way, very intense signals (e.g., of lipids) may obscure the small metabolite signals by leaking over several voxels. Appropriate weighting in k -space diminishes these effects, but decreases the spatial resolution somewhat.

3.1.4.3 Chemical shift. Slice selection with frequency-selective pulses and gradients shifts the slices of spins with different chemical shifts over a distance proportional to the ratio of their chemical shift and the gradient strength. For protons at 1.5 T, with a relevant chemical shift range of about 5 ppm, and a gradient strength of 10 mT m^{-1} , this displacement is about 1 mm. This is insignificant with respect to the VOI size of about 1 cm, but at higher field strengths, or for nuclei with larger chemical shift ranges (^{31}P and ^{13}C), this is no longer the case.

When the rf pulse bandwidth is not large compared with the chemical shift difference of coupled spins, multiplet components in different parts of the VOI are differently refocused in echo experiments, resulting in considerable signal loss.⁵⁸ Consider, for instance, lactate in the 3D PRESS experiment, with an rf pulse bandwidth of 1 kHz, and an echo time of 138 ms; at 1.5 T, 9%, and at 4 T, 24% of the CH_3 signal is lost.

It is obvious that localization errors will be more important when the sample is more heterogeneous. To minimize these errors, phantoms and spectroscopic or imaging techniques can be used to determine the size, shape and position of the selected VOI, and contamination and signal loss upon localization.⁵⁶

3.1.5 Motions

These degrade the localization performance in single voxel single shot MRS; in multishot add-subtract experiments like ISIS⁵⁵ this effect is further increased. In MRSI,⁵⁷ motions produce large artifacts and contamination in the spectra of each voxel, and ghosting in the spectroscopic images. The effects of motions can be minimized by using single shot experiments, short echo times, and methods that trigger from the motion, as used in MRI.

3.1.6 J Modulation Effects

Transverse multiplet components of scalar-coupled spins dephase under the influence of the coupling. This dephasing is not refocused, partly refocused, or totally refocused in multipulse experiments, depending on pulse distances,⁵⁹ the offset frequencies of the spins, and the bandwidth of the refocusing pulses.⁵⁸ J modulation effects may therefore lead to complex modulation patterns in multipulse localization experiments; the several spectral components are phase and amplitude-modulated in different ways—the modulation depending on coupling constants, chemical shifts (in case of strong coupling), pulse delays and pulse angles. Moreover, if the spectral components are not all resolved then (partial) cancellation of signals with different phases may result.⁴³ The resulting intensity distortions therefore also depend on the B_0 homogeneity; see Figure 3.

The intensity distortions can be determined experimentally on model solutions under well-defined conditions,⁴³ and used to correct the observed signal strengths, or as prior information in the NLLS fitting techniques to improve the accuracy. The linewidth has to be carefully controlled to keep the (partial) cancellation of signals with phase abnormalities comparable.^{12,43}

3.1.7 Frequency-dependent Intensity Distortions by the Applied Pulse Sequence

Well-known examples are several water-suppressing pulse sequences. The effect can either be calculated or determined experimentally, allowing a correction.

Figure 3 Real parts of the spectra obtained after FT of the 1.5 T γ and β simulated proton signals of glutamate: (a) and (b) were obtained after a single 90° pulse applied to the spin system in its equilibrium state; (c) and (d) were obtained from the echoes after a PRESS sequence with an echo time of 55 ms. In (a) and (c), the Lorentzian linewidth is 1 Hz; in (b) and (d), it is 3 Hz. The integrals of the spectra (a) and (b) are 16.4 and 16.3 (arbitrary units); the integrals of the absolute value mode signals corresponding to (c) and (d) are 13.6 and 7.8 (arbitrary units). Note the considerable signal loss in (d) as a result of phase anomalies due to J modulation combined with line overlap

3.1.8 Decoupling, Static, and Dynamic Nuclear Overhauser Effects; Exchange

Proton decoupling may result in completely different spectral patterns and intensity ratios in ^{31}P and ^{13}C spectra due to the decoupling and the heteronuclear Overhauser effect. Water suppression by selective inversion of the water resonance, followed by a relaxation delay to null the water signal, may result in distorted lineshapes and metabolite dependent intensity changes due to a dynamic nuclear Overhauser effect and/or exchange of protons. These effects can, in principle, be corrected for by determining them experimentally. See also *Magnetization Transfer and Cross Relaxation in Tissue; Proton Decoupling in Whole Body Carbon-13 MRS; Proton Decoupling During In Vivo Whole Body Phosphorus MRS.*

3.1.9 Partial NMR Visibility

Metabolites with short T_2 values are visible as broad lines in the spectrum, or are totally invisible. For instance, the lipid signals in the normal brain in ^1H MRS are invisible, bone from the skull shows up as a broad peak in ^{31}P MRS, and glutamate is only about 65% NMR-visible in the ^1H spectrum of rat brain.⁶⁰ Corrections for (partial) NMR visibility are difficult.

3.2 Relative and Absolute Metabolite Concentrations

In this section, it is assumed that the corrections for distortions as described in Section 3.1 have been performed as far as

possible. Relative metabolite concentrations are then obtained as signal intensity ratios, and often reported as such. This is a simple procedure, but global concentration changes are obscured. Absolute metabolite concentrations are of more clinical importance when tissue destruction or cellular damage is expected,¹¹ and allow better comparison of data from different studies. By acquiring, besides the metabolite signals, the signal of an internal or external reference compound with known concentration and volume, the instrument-dependent relation between signal intensity and concentration can be calibrated, and absolute concentrations obtained. Before discussing this further, some general remarks will be made.

1. To compare concentrations, the volumes occupied by the reference compound and the metabolites both have to be taken into account. These volumes can be determined by imaging. MRS localization errors may be different for the two volumes.
2. The detected NMR signal is an average over the VOI; biological tissue is heterogeneous, and the distribution over the VOI may be different for the reference and the several metabolites.
3. Signal intensity corrections as described in the previous section for both the reference and the metabolites have to be performed.
4. Loading modifies the rf field strength and coil sensitivity. By measuring the loaded and unloaded quality of the coil, or by mimicking coil loading by phantoms with conducting solutions,^{11,61} a correction is possible.

3.2.1 Internal Reference

The use of an endogenous reference with a known concentration is the simplest way to obtain absolute metabolite concentrations. The PCr/Cr peak, NAA, or tissue water have been used for ^1H NMR, ATP, and also tissue water (as a heteronuclear reference) for ^{31}P MRS.^{11,61} An internal reference has the advantages that the same experimental conditions and volume hold for reference and metabolites, making corrections for localization, rf inhomogeneity, and loading superfluous. A heteronuclear reference needs correction for the different resonance frequencies.¹¹ Disadvantages are that concentration and relaxation times of the reference may change with pathology and physiology. The reference peak may also contain signals from other compounds, an example being a contribution of *N*-acetylaspartylglutamate to the NAA peak.³ The spatial distributions of reference and metabolites can be different.

3.2.2 External Reference

Several procedures have been described.^{3,11} One possibility is to acquire together with the in vivo signal, a signal from a reference with known concentration and volume in a capillary close to the coil.⁶² In a separate experiment, the patient is replaced by a phantom containing a known metabolite concentration. The same VOI is localized as in the in vivo experiment, acquiring signal from capillary and phantom. Relating the four signals gives the absolute concentrations. Alternative methods and corrections for partial volume effects when using water as reference can be found in the literature.^{63–65}

3.2.3 Some Absolute Concentrations

The above considerations might give the impression that the determination of absolute concentrations by MRS is hardly possible. It is possible within the limitations mentioned, but it requires a lot of effort. In several studies, absolute concentrations have been reported,^{3,11} and satisfactory agreement with other analysis methods was obtained. Some literature values of metabolite concentrations for normal adult human brain obtained from ¹H MRS are⁴⁵ (in mmol kg⁻¹) NAA 8.9 PCr + Cr 7.5, and Cho 1.3. For ³¹P, adult human brain concentrations found were¹¹ (in mmol kg⁻¹) PME $\approx$ 3.5, Pi $\approx$ 2.0, PDE $\approx$ 11.0, PCR $\approx$ 4.5, and NTP (nucleotide triphosphates) $\approx$ 3.0; the corresponding values for human skeletal muscle are 2.2, 5.2, 4.2, 34, and 6.8 mmol kg⁻¹. For more data, see the review papers.^{3,11,45}

Rotating Frame Methods for Spectroscopic Localization

Peter Styles

MRC Biochemical and Clinical Magnetic Resonance Unit, Oxford, UK

1 INTRODUCTION

Rotating frame spectroscopic localization techniques enable high-resolution spectra to be obtained from spatially resolved slices within a sample. In contrast to most localization schemes where space is encoded by means of switched gradients in the B_0 field, the rotating frame method uses a gradient rf transmitter field (B_1) to effect the spatial discrimination. Most applications have been in ^{31}P spectroscopy of metabolism of animals and humans. Being a one-dimensional (spatial) technique, the method is most appropriately employed in situations where the anatomy consists of approximately planar tissues.

In the late 1970s, there was great interest in developing methodologies for NMR imaging, and the concept of using a gradient B_1 field to encode position was proposed by Hoult.¹ He demonstrated that a two-dimensional proton image could be produced by defining one dimension by a static B_0 gradient, and the second dimension by a gradient transmitter field. A straightforward modification of this 'rotating frame zeugmatography' was to apply the method to spectroscopic localization. The B_0 read gradient was omitted, preserving the chemical shift information at the expense of one dimension of spatial resolution.² Spatial encoding is achieved by applying, in separate data acquisitions, an incremented transmitter pulse, and performing a two-dimensional Fourier transformation to obtain a plot of chemical shift versus B_1 strength. Thus, rotating frame spectroscopic imaging is a one-dimensional chemical shift imaging (CSI) technique. A second form of implementation enables spectra to be obtained from just a limited number of regions by combining data which together form a Fourier series defining the required voxel shape and position.³

A review article⁴ provides a more comprehensive reference list than can be accommodated here.

2 PRINCIPLES OF ROTATING FRAME SPECTROSCOPIC LOCALIZATION

2.1 Rotating Frame Spectroscopic Imaging

When a nuclear spin is irradiated by a transmitter field at the Larmor frequency, then, in the rotating frame of reference,

the spin precesses around the B_1 field at a nutational frequency Ω given by

$$\Omega = \gamma B_1 \quad (1)$$

In a homogeneous B_1 field, detection of this frequency is trivial, and is undertaken every time one determines a $\pi/2$ pulse length. Signal amplitude is measured as a function of pulse duration, and a plot of amplitude versus pulse length produces a sine wave of frequency Ω .

If, instead of using a conventional probe, we employ a transmitter coil which produces a gradient in, say, the x direction [$B_1 = f(x)$], then the nutational frequency is directly related to the position of the sample along the x axis:

$$\Omega = \gamma f(x) \quad (2)$$

Detection of Ω is again a simple matter of determining signal amplitude as a function of pulse length, but we now have a range of frequencies reflecting the distribution of the sample in the gradient field. Therefore, a Fourier transform is required to interpret the variation of amplitude with pulse length. The result of this transform is a plot of amplitude versus Ω , and so represents the signal strength as a function of B_1 and hence position in the x direction.

The experimental sequence may be represented as

$$r\theta_x - \text{Acq. } (r = 1, \dots, n) \quad (3)$$

where the pulse θ_x is increased by incremental steps in each of n data accumulations. In the general case, where the sample consists of various chemical species, a two-dimensional Fourier transform of these n FIDs produces a data set with chemical shift on one axis and position in the x direction on the other. The protocol is illustrated in Figure 1, and was the first to be used for obtaining chemical shift images from a human.⁵

2.2 Phase-Modulated Rotating Frame Imaging

The experiment described by sequence (3) produces signals which are amplitude modulated as a function of Ω , and this incurs an inevitable loss in sensitivity. The maximum signal is only recovered when $r\theta_x$ is an odd multiple of $\pi/2$, and passes through a null for even multiples of $\pi/2$. This disadvantage can be avoided by converting the amplitude modulation into phase modulation by using the following pulse sequence:

$$r\theta_x - (\pi/2)_y - \text{Acq. } (r = 1, \dots, n) \quad (4)$$

The second pulse, which is not incremented, rotates the magnetization from the zy plane into the xy plane, and thus the maximum signal is obtained irrespective of the tip angle generated by the $r\theta_x$ pulse. This 'phase-modulated rotating frame' protocol^{1,6} is illustrated in Figure 2.

One difficulty of the phase-encoded sequence is that the data generate phase twisted lines with dispersion components obscuring both spectral and spatial information. The solution is to repeat the complete sequence with the phase of one of the pulses altered by π . To process the data, each set of FIDs is separately transformed, one transform is then reversed in the spatial dimension and the two sets added. The dispersion components now subtract to obtain pure absorption spectra.

2.3 Fourier Series Methods

In certain instances, it is sufficient to obtain signals from a limited number of slices, and then the rotating frame method can be implemented in a simpler way. Instead of collecting a full two-dimensional data set, transmitter pulses may be chosen such that the region of interest experiences tip angles which are odd multiples of $\pi/2$. Appropriate combination of the several FIDs (addition or subtraction, depending on the sign of the signal) will result in the maximum signal from the region of interest, but destructive interference of signals from elsewhere. The shape and extent of the sensitive region is determined by the number of pulse angles used, and the weighting function applied to successive data acquisitions. In essence, the spatial response of each collection forms a Fourier component of the final selected region, and so the technique is usually described as the 'Fourier series window' method.³ Provided that a reasonable number of FIDs have been collected, it is possible to combine them in different ways, thus defining more than one window from a single data set. Developments of this approach have included the use of adiabatic pulses to reduce artifacts, and a combination of B_0 and B_1 techniques to improve slice definition.⁷

2.4 Relaxation Time Measurements and Magnetization Transfer Sequences

The basic rotating frame sequences can be combined with saturation, inversion or spin echo pulses, thus facilitating the determination of spatially localized relaxation times, or providing a means of spectral editing. One of the benefits of B_1 localization over B_0 methods is that no time is lost waiting for gradient recovery, and therefore nuclear species with short relaxation times may be detected and quantitated.⁸

Magnetization transfer experiments may also be implemented,⁹ giving localized measurement of certain chemical exchange processes in vivo.

3 ROTATING FRAME LOCALIZATION IN PRACTICE

3.1 Probes for Rotating Frame Spectroscopy

The generation of a linear gradient in the B_1 field is less straightforward than in the B_0 field. Hoult¹ used a saddle-shaped transmitter coil with three turns on one side and one turn, wound in the opposite sense, on the other. To perform the phase-encoded protocol, a second orthogonal transmitter coil is needed to generate the $(\pi/2)_y$ pulse. This arrangement has never been used for in vivo spectroscopy due to the excessive amounts of rf power which would be required. Instead, surface coils have been used for production of the B_1 gradient. This approach is, at best, a pragmatic solution on several counts. First, a surface coil does indeed provide a gradient field, but it is only approximately linear over a restricted region of space. Secondly, although the isofield contours are relatively flat close to the axis of the coil, they curve towards the plane

Figure 1 The acquisition of rotating frame imaging data from a phantom. (a) Schematic representation of a two-compartment phantom placed in a gradient B_1 transmitter field. (b) A set of 'pulse and collect' spectra obtained from the phantom; the pulse length is incremented in successive data collections. (c) The data generated by performing a second Fourier transformation on the set of spectra shown in (b). The vertical axis represents the frequency with which the signal modulates as a function of the increasing pulse length, and therefore displays the position of the phantom in the gradient B_1 field. (Reproduced by permission of Springer-Verlag from P. Diel, E. Fluck, H. Gunther, R. Kosfeld, and J. Seelig (eds), 'In Vivo Magnetic Resonance Spectroscopy. II: Localization and Spectral Editing', Berlin, 1992, p. 45)

of the coil away from this central region. Finally, the phase encoding experiment ideally needs a homogeneous pulse in addition to the gradient pulse for spatial encoding. These problems constitute substantial drawbacks, but the particular

Figure 2 A comparison of spectra collected by (a) amplitude and (b) phase-modulated protocols. The data were obtained from the same phantom as in Figure 1, and are sets of individual spectra prior to the second Fourier transformation. Note that the full signal strength is obtained at all pulse lengths in the phase-modulated experiment. (Reproduced by permission of Springer-Verlag from P. Diel, E. Fluck, H. Gunther, R. Kosfeld and J. Seelig (eds), 'In Vivo Magnetic Resonance Spectroscopy. II: Localization and Spectral Editing', Berlin, 1992, p. 45)

suitability of the surface coil for in vivo spectroscopy has encouraged workers to devise methods which maintain the integrity of the experiment within acceptable bounds. Three approaches have been adopted:

1. Single surface coil transmit/receive probes can be used, provided that the sample is restricted to a region close to the coil axis. This method is not of general application, but has been used, for example, to obtain information from the excised bovine globe.
2. A single surface coil probe may be used if some other localization strategy is incorporated into the protocol to restrict the localized volume to a column bounded within the surface coil perimeter. B_0 methods such as ISIS¹⁰ can be used to define the lateral extent of the detected signal, and rotating frame localization subdivides this region into planar slices.⁶

3. Separate surface coils for transmit and receive overcome many of the difficulties encountered.⁵ A surface coil transmitter produces a nearly linear field gradient over a region between about $0.3r_t$ and r_t (r_t is the radius of the transmitter coil), and close to the coil axis. If a smaller receiver coil is positioned coaxially with the transmitter, but offset by the appropriate amount, then the detected signals will come from this linear transmitter region. The two coils must, of course, incorporate suitable circuitry to avoid the electrical coupling caused by their mutual inductance.

3.2 Phase-Modulated Rotating Frame Implementation

The most efficient rotating frame protocol is the phase-modulated version, but this experiment requires a homogeneous $\pi/2$ phase-encoding pulse. In practice, the provision of yet another coil to produce this irradiation has been avoided. Instead, the phase-encoding pulse is usually applied by the gradient coil. Clearly, this will only produce an accurate $\pi/2$ rotation in a single plane. However, provided that the region of interest does not extend over too large a range of B_1 field, the experiment still gives good results. Away from the optimum plane, the main consequence is a small loss of sensitivity ($\leq 15\%$) where the phase-encoding pulse is within the range $\pi/4$ to $3\pi/4$.

An alternative solution to this problem is to employ an adiabatic pulse in place of the hard $\pi/2$ pulse.¹¹ B_1 insensitive plane rotation pulses are now available, their main drawback being that they are longer than hard pulses, and so introduce relaxation dependent losses into the sequence.

4 APPLICATIONS OF ROTATING FRAME METHODS

Rotating frame methods⁴ are most usefully applied in situations where a surface coil provides the optimum method of data collection, and the anatomy is suited to planar localization. In humans, the heart and liver have both been studied extensively. In each case, the tissue of interest needs to be distinguished from the overlying intercostal muscles. The liver is of particular note because, unlike muscle, it contains no creatine phosphate. Thus, the efficacy of the localization can be easily tested using the liver as an 'in vivo phantom' (Figure 3). In other studies of the human, spectra have been obtained from the brain, breast, leg muscle, and several types of tumor. A variety of disorders have been investigated, including heart failure, hepatic diseases, and trauma of the brain.

Many experiments have also been performed on animal models, perhaps the most striking being the detection of metabolite concentration differences across the ventricular wall of the exposed beating heart.^{12,13} Although most studies have used the phosphorus nucleus, carbon, fluorine, and sodium spectra have also been obtained.

The absence of time-consuming switched field gradients is important for the detection and measurement of short T_2 species such as the broad phosphodiester resonances in brain.⁸ In the liver, proton spin echo rotating frame spectroscopy has

Figure 3 A phase-modulated rotating frame spectroscopic image obtained from the chest of a human subject in the region where the intercostal muscles overlie the liver. The data are presented as: (a) a stacked plot of the spectra; (b) a contour plot; (c) a single spectrum from the muscle region; (d) a single spectrum from the liver region. Peak assignment: 1, phosphomonoesters; 2, inorganic phosphate; 3, phosphodiester; 4, creatine phosphate; 5–7, mainly adenosine triphosphate. Note the localization of the creatine phosphate to the superficial region corresponding to the intercostal muscles

been used to quantitate iron overload,¹⁴ which manifests itself by a dramatic decrease in the T_2 of water.

5 THE ROLE OF ROTATING FRAME TECHNIQUES

Techniques for localized spectroscopy have undergone considerable development over the last 10 years, and it is instructive to consider both the merits and disadvantages of rotating frame methods in comparison to other localization schemes.

There is no doubt that the rotating frame approach lacks the versatility of phase-encoded Fourier imaging using switched B_0 field gradients. B_1 methods give localization in only one dimension, suffer from off-resonance effects, and often require specialized hardware in the form of multicore probes. Also, there is no direct correlation between the localized spectroscopic data and anatomical information obtained from an MRI image taken during the same investigation.

On the other hand, the absence of switched gradients imparts several benefits. The signal is collected immediately after the transmitter pulse, thus avoiding phasing problems and

loss of signal due to T_2 effects. The experiment is silent, which can be particularly important when a subject is nervous or young. Finally, the localization is defined relative to the probe (as distinct to the magnet), and so moving objects such as the chest wall or exposed beating heart can be scanned by attaching the probe directly to the tissue.

Therefore, rotating frame localization is a technique which does not match the generality of B_0 Fourier methods, but can offer very significant advantages in specific applications such as those outlined above.

Single Voxel Localized Proton NMR Spectroscopy of Human Brain In Vivo

Jens Frahm and Wolfgang Hänicke

Biomedizinische NMR Forschungs GmbH am Max-Planck-Institut für Biophysikalische Chemie, Göttingen, Germany

1 INTRODUCTION

The unique potential of in vivo NMR for the life sciences is based on true noninvasiveness and tremendous methodologic flexibility. A continuous flow of novel techniques allows the addressing of fundamental questions related to structural, functional, and metabolic aspects of life processes within the intact human body. In particular, in vivo spectroscopy yields detailed insights into cellular metabolism of organ systems by combining the analytical strength of high-resolution NMR with image-controlled spatial localization within a three-dimensional object. Typically, localized proton NMR spectroscopy of human brain provides access to tissue metabolites with millimolar concentrations from a few milliliter volumes and within measuring times of less than 10 min.

Early studies employed surface radiofrequency (rf) coils¹ and homogeneity profiling of the static magnetic field² to assess bioenergetics via phosphate metabolites.^{3–5} Although the simple surface coil technique was applied to other organs and nuclei including proton NMR of human brain,⁶ optimum placement of a local rf antenna suffered severe limitations and often required surgical interventions as demonstrated by animal work.^{7,8} With the availability of well-controllable magnetic field gradients through advances in NMR imaging, improved localization methods took advantage of the principles of spatial encoding by magnetic field gradient pulses and slice selection by frequency-selective rf excitation in the presence of a magnetic field gradient. Two complementary approaches were developed that are able to accomplish three-dimensional spatial discrimination of the NMR signal:

- chemical shift imaging (CSI) techniques that cover a column, plane, or volume in a two- (2D), three- (3D), or four-dimensional spectroscopic image where spatial information is phase encoded onto the chemical shift information of the NMR frequencies,
- single voxel spectroscopy techniques that acquire spectroscopic time-domain data directly from a restricted volume of interest (VOI) selected prior to or during rf excitation.

The aim of this contribution is to discuss the mainstream of in vivo proton NMR spectroscopy techniques based on single voxel localization. The capability of performing human studies on whole body systems is ensured by emphasizing the compliance of pertinent sequences with safety requirements and instrumental limitations, e.g. in terms of rf power. Methodologic descriptions include an outline of specific merits and

pitfalls, while selected studies of human brain metabolism illustrate particularly advantageous applications.

2 LOCALIZATION TECHNIQUES

Beyond structure elucidation of biomacromolecules, NMR studies of biologic systems comprise body fluids, cell cultures, excised tissues, perfused organs, and intact living subjects (*Body Fluids, Cells and Cell Systems MRS*, and *Tissue NMR Ex Vivo*). Respective applications benefit from a widespread range of instruments and sequences and cover a large diversity of basic science and clinical questions. Even when restricting this complexity to single voxel proton NMR there are multiple factors that affect the design and outcome of localization techniques. This particularly holds true for differences in (i) hardware of small-bore high-field spectrometers and whole body instruments (see Section 2.5), (ii) relaxation times and available measuring times under in vitro and in vivo conditions, (iii) the extent of motion in nonliving materials, anesthetized animals, and human subjects, and (iv) cooperativity of healthy subjects and patients.

Thus, optimum strategies for localization sequences applicable to human subjects not only have to address relaxation losses and suppression factors, but also critically rely on practical simplicity and stability as crucial elements for ease of implementation and use as well as for the reliability of the results. Accordingly, the following sections discuss surface coil techniques and image selected in vivo spectroscopy (ISIS) for historic reasons, while special emphasis is paid to *point-resolved spectroscopy* (PRESS) and *stimulated echo acquisition mode* (STEAM) spectroscopy as the major localization techniques for single voxel proton NMR on whole body units.

2.1 Surface Coils and Beyond

The popularity of local rf antennae or 'surface' coils is based on the simplicity of the concept and the excellent signal-to-noise ratio (S/N; see *Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas*). However, from a technical point of view the latter benefit is not only due to a good filling factor but is also due to a sensitive volume extending far beyond the coil radius.⁹ In fact, the contributing volume is not even well-defined, since it strongly depends on the experimental parameters of the rf pulse sequence (e.g., repetition time, flip angle used) and the tissue T_1 relaxation times involved.¹⁰

Figure 1 depicts flip angle distributions of a single-turn surface coil for B_1 field strengths yielding flip angles of either 90° (top) or 180° (bottom) at a distance $r/2$ from the center of the coil. While pertinent flip angle distributions result in inhomogeneous *excitation* of transverse magnetizations, corresponding sensitivity distributions also affect the *acquisition* of the NMR signal by surface coil reception. Thus, transmit–receive use of an inhomogeneous coil leads to a quadratic dependence on B_1 which may be reduced to a linear dependence by combining surface coil detection with homogeneous excitation using a second circumscribing coil.

Assuming a transmit–receive situation, Figure 2 describes the sensitivity σ of a single-turn surface coil as a function of TR/T_1 and rf flip angle

Figure 1 Flip angle distribution of a single-turn flat surface coil (radius r) in the central xy plane perpendicular to the coil for two different B_1 field strengths adjusted such that the flip angle at a distance $r/2$ from the center of the coil is either 90° (top) or 180° (bottom). Iso- B_1 curves are given for selected flip angles in steps of 30° . The coil is oriented parallel to the static B_0 field (z axis). (Reproduced by permission of Academic Press from Haase et al.¹⁰)

$$\sigma = \iiint B_1(x, y, z) S(x, y, z) dx dy dz \quad (1)$$

with $B_1(x, y, z)$ the rf field distribution as demonstrated in Figure 1. $S(x, y, z)$ denotes the local strength of the FID of a repetitive single pulse experiment with equilibrium magnetization M_0 , flip angle α , repetition time TR , assuming the absence of transverse components (i.e., $TR > 3 T_2^*$)¹¹

$$S(x, y, z) = M_0 \sin \alpha(x, y, z) \frac{1 - \exp(-TR/T_1)}{1 - \exp(-TR/T_1) \cos \alpha(x, y, z)} \quad (2)$$

The spatial flip angle distribution

$$\alpha(x, y, z) = \gamma B_1(x, y, z) \tau_p \mu I / (2\pi) \quad (3)$$

has to be calculated according to Biot-Savart's law with γ the magnetogyric ratio, τ_p the pulse duration, I the current, and μ the permeability of the specimen.

Obviously, the strength of the detected NMR signal predominantly reflects the size of the excited volume. Regardless of the actual measuring parameters, the nonlocalized signal from the 'total' volume ($\sigma/TR \approx 75$, upper left in Figure 2) is considerably larger than that of a near (≈ 15 , lower left) or distant (≈ 8 , lower right) slice of thickness $r/5$ or that of a sphere of radius $r/2$ (≈ 4 , upper right) at a distance r from the coil cen-

ter. Assuming $TR/T_1 = 1$ the maximum *local* signal strength is in a 90° flip angle region close to the coil. However, although outer signal strengths are much smaller, their contributions to the received signal may easily overcompensate 'high-flux' regions close to the coil by simple volume considerations. Moreover, low flip angle excitations in outer regions effectively reduce the extent of signal saturation for acquisitions with $TR < 3 T_1$ and therefore further increase the relative contribution of unwanted signals distant from the coil. Thus, despite some gross anatomic localization of the NMR signal as given by the size and shape of the coil, it is not possible to focus properly on a desired VOI by a simple single pulse surface coil NMR experiment.

Of course, there are important biochemical questions that do not need exquisite spatial discrimination of tissue signals. Even nonlocalized experiments may provide the answer if relative changes are monitored during the course of a dynamic stimulus-driven study. Nevertheless, a number of refinements have been proposed to improve spatial selectivity of the basic surface coil experiment:

- slice-selective excitation and refocusing of the applied magnetic field gradient to select a plane parallel to the coil, depth resolved surface coil spectroscopy (DRESS);¹²
- slice-selective presaturation, fast rotating gradient spectroscopy (FROGS),¹³ and homogeneity spoiling by surface gradients¹⁴ parallel to the coil to eliminate signal contributions from superficial tissues (fat, muscle) between the coil and the target VOI;
- phase-cycled rf excitation and composite rf pulses ('depth' pulses¹⁵) to reshape the sensitive volume along the B_1 gradient of the coil;
- Fourier series windowed variants of the 'rotating frame imaging'¹⁶ experiment to profile spatially the acquired NMR signal along the B_1 gradient by multiple excitations with predefined flip angles (*Rotating Frame Methods for Spectroscopic Localization*).¹⁷⁻¹⁹

In summary, localization by placement of a surface coil is simple, easy to use, and provides good S/N. With single pulse rf excitation respective FID signals do not suffer T_2 relaxation losses. Potential pitfalls are (i) the uncontrolled extent of the sensitive volume as it depends on experimental parameters (TR , flip angle, tissue T_1), (ii) problems with absolute quantitation and comparability of studies, and (iii) limited or no access to inner organs. Most of these arguments also hold true for the refined versions mentioned above as they deliver one-dimensional (1D) solutions to a 3D problem.

Surface coils have mainly been applied in conjunction with phosphorus NMR studying alterations of cellular energy metabolism in skeletal muscle, liver, or heart (*Peripheral Muscle Metabolism Studied by MRS* and *Complex Radiofrequency Pulses*). In contrast, proton NMR studies of focal metabolism in brain require more sophisticated gradient-based localization techniques. While homogeneous rf coils are beneficial with respect to metabolite quantitation and study comparability, surface coils may still be used for sensitivity enhancement in a receive-only configuration. In fact, gradient-localized single voxel NMR techniques such as PRESS or STEAM are even possible in a transmit-receive mode. If the dimension of the VOI remains smaller than the surface coil radius, then localized

Figure 2 Sensitivity per unit time (σ/TR) as a function of TR/T_1 (logarithmic scale) and rf flip angle α for a transmit-receive single-turn flat surface coil. The NMR signal, as given in equation (1), is integrated over four different volumes: (upper left) 'total' volume covering linear dimensions of $2r$ and $4r$ perpendicular and parallel to the coil (radius r), respectively; (upper right) spherical volume of radius $r/2$ centered at a distance r from the coil center; (lower left) slice of thickness $r/5$ at a distance $r/2$ parallel to the coil; (lower right) similar slice at a distance r . The solid lines indicate maximum sensitivity. (Reproduced by permission of Academic Press from Haase et al.¹⁰)

optimization of the rf power ensures homogeneous rf excitation and signal reception.

2.2 Image-Selected In Vivo Spectroscopy (ISIS)

Prior to nonselective excitation by a 90° rf pulse (or any other rf scheme), the ISIS sequence²⁰ prepares the equilibrium magnetization of a 3D object by up to three slice-selective

180° inversion pulses in the presence of orthogonal magnetic field gradients. As outlined in Figure 3 the method requires a minimum of eight successive experiments to achieve spatial localization by adding/subtracting FID signals of properly prepared longitudinal magnetizations. The individual acquisitions correspond to 2^3 combinations (on/off) of the three inversion pulses. For example, subtraction of acquisitions #1 (no 180° pulse applied, excitation of the entire object) and #4 (magnetization inversion of a plane along the first gradient axis) results

Figure 3 ISIS localization sequence comprising three slice-selective 180° inversion rf pulses along orthogonal gradient axes. A Gaussian shape has been chosen for schematic drawing only, while frequency-modulated pulses of the hyperbolic-secant type are most frequently employed. The measured NMR signal is excited by a final 90° read pulse. For full three-dimensional localization the ISIS sequence needs to be repeated at least eight times using inversion pulses on/off in all three gradient axes (2^3 combinations) with proper setting of the receiver phase (add/subtract)

in twice the signal from a plane perpendicular to the first gradient axis, whereas all signals outside the inverted area have the same phase and thus cancel.

In its original form the ISIS method is only valid for fully relaxed acquisitions with $TR > 3 T_1$. This is due to the fact that incomplete recovery of the longitudinal magnetization prior to a subsequent preparation period affects the resulting longitudinal magnetization. Since preparation of the longitudinal magnetization is different for the eight experiments, the cancellation of unwanted signal remains incomplete and also depends on the order in which the eight acquisitions are performed. This problem may be solved by a postacquisition saturation or 'magnetization purging' pulse²¹ eliminating any residual longitudinal magnetization in between ISIS acquisitions. Further improvements are due to the use of frequency-modulated 'adiabatic' inversion pulses^{21,22} that sharpen the spatial profiles of the inverted planes. In addition, signal contamination from outside the VOI has been attenuated by means of outer volume suppression schemes, in particular by using noise-modulated rf excitation in combination with dephasing gradients.²³

The main advantage of the ISIS approach is the use of the FID since it avoids signal losses for metabolite resonances with short T_2 relaxation times as frequently observed in vivo. Only very small T_1 relaxation losses occur during the initial preparation period. Effective decoupling of localization from excitation in the ISIS sequence provides potential for combi-

nations with more complex multipulse excitation sequences including spectral editing techniques. Major disadvantages of ISIS originate from its multishot character and the fact that localization of a small VOI signal is accomplished by subtraction of large signals from almost the entire object. Thus, the technique may lead to substantial signal contamination and shows considerable sensitivity to motion-induced localization errors. Signal contamination may also arise from spins within inverted planes but outside the VOI through T_1 relaxation between inversion and excitation. Moreover, the excited though unwanted signal outside the VOI increases with decreasing size of the VOI. Finally, localized optimization of magnetic field homogeneity and water suppression as well as online monitoring of dynamic acquisitions are precluded as they require single-shot capabilities.

Despite some useful technical improvements, applications of single voxel ISIS spectroscopy have been mainly directed toward phosphorus NMR with only rare applications to proton NMR of human brain.^{24–28} Figure 4 shows ISIS proton NMR spectra of a patient with chronic infarction²⁷ where the nonselective 90° excitation pulse has been replaced by a semiselective spin echo sequence with different echo times TE . The excited frequency range was centered between the methyl resonances of *N*-acetylaspartate (NAA) and lactate to improve water suppression and to eliminate homonuclear J modulation of the lactate doublet at 1.33 ppm weakly coupled to the nonexcited methine quartet at 4.12 ppm.

Figure 4 Localized proton NMR spectra of a patient with a chronic infarction at different echo times (TE) obtained using ISIS with outer volume suppression pulses and semiselective spin echo excitation. Other parameters: 2.0 T, VOI $40 \times 25 \times 30 \text{ mm}^3$, $TR = 3000 \text{ ms}$, 256 transients. Frequency-selective excitation was centered between the methyl resonances of *N*-acetylaspartate (NAA) and lactate thereby eliminating J modulation of the lactate doublet at 1.33 ppm. Water suppression was achieved by an initial DANTE presaturation sequence. The patient spectra demonstrate a reduced NAA/creatine ratio and a strong contribution from lactate. (Reproduced by permission of Academic Press from Sappey-Marini²⁷)

2.3 Point-Resolved Spectroscopy (PRESS)

In vivo proton NMR spectroscopy of human brain is more demanding in terms of localization acuity and lack of outer volume contamination than usually can be fulfilled by surface coil and ISIS localization strategies. On the other hand, potential problems due to T_2 attenuation are considerably reduced since proton resonances of cerebral metabolites exhibit much longer T_2 relaxation times than in skeletal muscle, liver, and heart or are found in phosphorus NMR. PRESS and STEAM sequences therefore achieve localization by integrating slice selection and spectral excitation. Both methods directly excite the NMR signal from the desired VOI in a single 'shot' rather than attempt to saturate or subtract the much larger signal from outer volumes. In addition, PRESS and STEAM lend themselves to a user-friendly and partially automated spectroscopy examination ranging from image selection and VOI definition to spectral evaluation and quantitation.

Figure 5 shows a basic rf pulse and gradient scheme for a PRESS localization sequence^{29,30} comprising slice-selective

90° rf excitation, dual slice-selective 180° rf refocusing, and acquisition of the resulting secondary spin echo (SE). The VOI is defined by the intersection of three orthogonal planes since only spins that experience all three rf pulses refocus as a SE signal at the double echo time $TE = TE_1 + TE_2$. To avoid multiple quantum interferences caused by imperfect slice-selective refocusing pulses with non- 180° flip angles, the echo time TE_1 of the first SE should be chosen as short as possible (see Section 3.2). Similar arguments hold true for a reduction of motion sensitivity (see Section 3.3). In most cases only the second half of the SE is acquired. This is due to the fact that proton signals of a well-shimmed VOI in brain exhibit rather long T_2 relaxation times, so that even for long echo times such as $TE = 270 \text{ ms}$ the leading part of the SE signal becomes truncated by the localization sequence itself.

For proton NMR spectroscopy of metabolites the PRESS sequence has to be combined with water suppression. While a variety of techniques including differential relaxation, binomial excitation, and frequency-selective saturation by long pulses or pulse trains have been employed on spectrometers without shaped rf pulse capabilities, the most convenient method on modern NMR systems is the use of chemical shift selective (CHESS) water suppression.³¹ The method is based on frequency-selective excitation of the resonance to be suppressed by an amplitude-modulated rf pulse followed by dephasing of the created transverse magnetization by spoiler gradients. For maximum water suppression several CHESS cycles may be applied immediately prior to the localization sequence.

The PRESS proton NMR spectra of parietal white matter of a normal human subject are shown in Figure 6 for a short (top) and long (bottom) echo time. Resonances have been assigned to *N*-acetylaspartate (NAA), creatine and phosphocreatine (Cr), choline-containing compounds (Cho), *myo*-inositol (*myo*-Ins), and glutamate/glutamine (Glx). The resonance at about 4.7 ppm represents the residual water proton signal which is further attenuated by T_2 relaxation at the echo time of $TE = 270 \text{ ms}$.

The PRESS sequence represents a single-shot method that is easy to use on commercial whole body NMR systems including image selection and *localized* optimization of magnetic field homogeneity and water suppression. Since PRESS excites only those magnetizations that contain the desired VOI as part of an excited slice, most of the outer volume equilibrium magnetization remains unaffected. Gradient spoiling is applied to FID signals from outside the VOI that are due to the first 90° rf pulse as well as caused by imperfect 180° rf pulses. In contrast to ISIS, this problem decreases with decreasing size of the VOI as determined by three slice thicknesses. Of course, PRESS suffers from T_2 relaxation losses the extent of which depends on the chosen echo time, while coupled spins may be subject to substantial J modulation.

2.4 Stimulated Echo Acquisition Mode Spectroscopy (STEAM)

In close analogy to the PRESS technique, STEAM sequences define the VOI by the intersection of three planes excited by sequential application of slice-selective 90° rf pulses.³²⁻³⁴ The schematic diagram shown in Figure 7 refers to a short echo time version corresponding to $TE \approx 10\text{--}30 \text{ ms}$. Retransformation of transverse magnetization excited by the first pulse into longitudinal magnetization components by the

Figure 5 PRESS localization sequence comprising a slice-selective 90° rf excitation pulse followed by two slice-selective 180° rf refocusing pulses along orthogonal gradient axes. In most cases only the second half of the secondary spin echo (SE) occurring at the echo time $TE_1 + TE_2$ is acquired

second pulse retains the phase information acquired during $TE/2$, but subjects the signal to T_1 relaxation during the middle interval TM . The FID associated with the second pulse is dephased by application of spoiler gradients during TM that also eliminate unwanted spin echoes. Application of the third pulse leads to two types of transverse magnetization. Firstly, components that carry phase information from the first $TE/2$ interval refocus after a total echo time (TE) as a stimulated echo (STE) attenuated by T_2 (and T_1) relaxation. Secondly, the FID from the equilibrium magnetization of the third slice outside the VOI as well as from T_1 -relaxed longitudinal magnetizations during TM is dephased by the gradients following the third pulse (compare Figure 7).

It is important to note that proper functioning of the STEAM sequence requires complete dephasing of the transverse magnetization prior to application of the second rf pulse. Only randomization of transverse components ensures an equal distribution of spin moments that subsequently form the SE signal from the first two rf pulses (dephased during TM) and the STE signal following all three pulses. In the original work on stimulated echoes³⁵ dephasing was fulfilled by extremely poor magnet homogeneity, but has not been mentioned as a 'necessary condition' for generation of a STE signal without modulations due to resonance offsets. In fact, in the case of complete spin rephasing during $TE/2$ and on-resonance excitation of a single resonance such as water, the first two pulses of the STEAM sequence would effectively add to yield a 180° inversion. Application of the third pulse then results in a FID of the actually recovered magnetization in very much the same way as in an inversion-recovery T_1 experiment. Of course, no STE signal would be observable.

It is for the above reason that the slice-selective gradients for the second and third pulse in Figure 7 are refocused after

the third rf pulse and prefocused before the second rf pulse, respectively. Since pertinent gradient pairs encode motion by inducing phase differences, it is advisable to keep TM as short as possible (also helpful to avoid T_1 losses) and as long as necessary to eliminate unwanted SE and FID signals by gradient spoiling. Typical values of $TM \approx 10$ – 30 ms depend on system hardware (gradient strength) and eddy current performance.

For STEAM acquisitions at extremely short echo times, e.g. $TE = 3$ ms, refocusing of the initial transverse magnetization may be accomplished after the third rf pulse as demonstrated for the other two directions in Figure 7. Of course, a substantial reduction of TE also involves shortening of rf pulse durations which often is at the expense of slice profile (VOI) quality. Pertinent applications may be advantageous for proton NMR in the presence of unavoidable motions, e.g. in abdominal organs, or for nuclei with short T_2 relaxation times such as phosphorus.³⁶ At long echo times care should be taken to keep the motion sensitivity to a minimum. Independence of TE may be accomplished by arranging respective slice-selective gradient pairs closely around the TM interval.

Figure 8 shows STEAM proton NMR spectra of parietal white (top) and gray matter (bottom) of a young healthy adult. Water suppression has been accomplished by three CHESS pulses preceding the STEAM localization sequence³⁴ in agreement with a detailed analysis of various suppression schemes.³⁷ In fact, CHESS pulses may also be incorporated into the TM interval, where longitudinal magnetizations are already restricted to a column.³⁸ Although such additional water suppression pulses slightly prolong the TM interval, they may be advantageous when using inhomogeneous rf coils.

Major resonances in proton NMR spectra of human brain are due to NAA, *N*-acetylaspartylglutamate (NAAG), glutamate

Figure 6 Localized proton NMR spectra of parietal white matter of a normal subject obtained using a PRESS sequence at $TE_1 + TE_2 = 30$ ms (top) and $TE_1 + TE_2 = 270$ ms (bottom). Other parameters: 2.0 T, VOI $25 \times 25 \times 25$ mm³, $TR = 1500$ ms, 256 transients. Resonances are due to: *N*-acetylaspartate (NAA), creatine and phosphocreatine (Cr), choline-containing compounds (Cho), *myo*-inositol (*myo*-Ins), glutamate/glutamine (Glx), and residual water at 4.7 ppm. (Courtesy of T. Ernst and J. Hennig)

(Glu), Cr, Cho, glucose (Glc), *scyllo*-inositol (*scyllo*-Ins), and *myo*-inositol (*myo*-Ins). Resonance assignments involved high-resolution high-field NMR spectra of tissue extracts from experimental animals and human biopsies as well as investigations of model solutions under the same conditions as used in vivo.^{7,39–42} Further work is required to assign unambiguously additional resonances in the aromatic part of the spectrum as well as aliphatic resonances from mobile lipids and/or cytosolic proteins, while resonances from metabolites such as lactate, glutamine, and alanine become detectable when elevated in disease states of the brain. Further examples of STEAM spectra are given in Sections 3 and 4 discussing effects of strong spin–spin coupling and advantageous applications of single voxel proton NMR as compared with CSI, respectively.

In summary, the basic advantages of STEAM localization are identical to those of PRESS sequences (see Section 2.3). A special merit stems from the excellent definition of the STEAM VOI via slice-selective 90° rather than 180° rf pulses. This feature translates into even less practical problems with signal

contamination, e.g. when selecting a VOI position close to the lipid-containing skull. Moreover, STEAM sequences allow shorter echo times than PRESS when using the same hardware (gradient strength, pulse durations, etc.). This is a benefit from the TM interval in STEAM as opposed to the two echo intervals TE_1 and TE_2 in PRESS. Another advantage relative to PRESS is due to the fact that STEAM sequences result in only half the J modulation of PRESS sequences at the same echo time (see Section 3.1), which considerably improves the detectability of homonuclear spin-coupled resonances in short echo time proton NMR spectra of tissue metabolites. This particularly applies to strongly coupled multiplets suffering from incomplete refocusing and signal loss at longer echo times. A typical example at 2.0 T is given by the Glu methylene resonances in the 2.0–2.5 ppm range which are much more reliably resolved in the STEAM $TE = 20$ ms spectrum (Figure 8) than in the PRESS $TE = 30$ ms spectrum (Figure 6), where J modulation corresponds to that of a STEAM sequence at $TE = 60$ ms.

On the negative side, STEAM results in only half the signal strength of PRESS at the same echo time. Of course, this theoretical value only holds true for exactly the same VOI: improved spatial discrimination by slice-selective 90° rf pulses in STEAM should not be mistaken as loss of signal. The STEAM technique also exhibits very small T_1 relaxation losses of the order of $[1 - \exp(-1/50)]$ or about 2%. Thus, PRESS sequences are recommended for acquisitions at long echo times (e.g. $TE = 135$ – 270 ms), while STEAM sequences demonstrate superior performance at short echo times (e.g. $TE = 20$ ms). With respect to ISIS it is worth noting that spatial discrimination of the VOI by direct excitation with PRESS and STEAM is independent of the power of the rf excitation pulses, so that deviations from 90° or 180° flip angles reduce the resulting VOI signal but do not compromise localization acuity.

2.5 Miscellaneous Methods

This section gives a brief overview of miscellaneous localization techniques that have been described in the literature. Although of theoretical interest, many sequences suffer from practical limitations and therefore have only been applied to phantom or animal studies performed on small-bore NMR systems. In particular, a whole class of experiments relies on the use of ‘hard’ nonselective rf pulses that require strong rf power to be of sufficiently short duration/large bandwidth for equivalent manipulation of unwanted spins outside the desired section. Pertinent localization techniques comprise a threefold application of a sequence module [A] in order consecutively to restore longitudinal magnetization within selected sections along orthogonal gradient axes. Since localization sequences of the type

$$[A]_x - [A]_y - [A]_z - \text{excitation} \quad (4)$$

decouple spatial selection and signal excitation, the final rf excitation sequence may be as simple as a 90°(nonsel)-FID sequence or comprise water suppression by frequency-selective excitation. While ISIS resembles a sequence of type (4) with use of slanted 180° inversion pulses, a parent method with

Figure 7 Short echo time STEAM localization sequence comprising three slice-selective 90° rf pulses along orthogonal gradient axes. Only the second half of the stimulated echo (STE) occurring at the echo time (TE) is acquired. The transverse magnetization excited by the first rf pulse is retransformed into longitudinal components by application of the second pulse, so that the intensity of the STE is subject to T_1 attenuation during the middle interval (TM) and to T_2 attenuation during TE

nonselective rf pulses is volume selective excitation (VSE).⁴³ The sequence employs a pulse package [A] according to⁴⁴

$$45^\circ_{x'}(\text{sel}) - 90^\circ_{-x'}(\text{nonsel}) - 45^\circ_{x'}(\text{sel}) \quad (5)$$

where the two selective 45° rf pulses represent the first and second half of a symmetrically selective 90° rf pulse, e.g. an amplitude-modulated pulse of Gaussian shape. Further examples are *spatially resolved spectroscopy* (SPARS),⁴⁵

$$90^\circ_{x'}(\text{nonsel}) - 180^\circ_{y'}(\text{nonsel}) - 90^\circ_{-x'}(\text{sel}) \quad (6)$$

spatial and chemical-shift-encoded excitation (SPACE),⁴⁶

$$90^\circ_{x'}(\text{sel}) - 180^\circ_{y'}(\text{nonsel}) - 90^\circ_{-x'}(\text{nonsel}) \quad (7)$$

and symmetric pulses for *accurate localization* (SPALL),⁴⁷

$$90^\circ_{x'}(\text{nonsel}) - 180^\circ_{y'}(\text{sel}) - 90^\circ_{-x'}(\text{nonsel}) \quad (8)$$

'DIGGER'⁴⁸ is an analog of VSE using frequency-modulated sin-sinc rf pulses with reduced rf power requirements.

A further class of experiment takes advantage of outer volume suppression such as *localization of unaffected spins* (LOCUS),⁴⁹ where series of slice-selective 90° rf pulses with overlapping excitation profiles are required in each direction to saturate all spins outside the desired VOI. Similar ideas apply to 'ROISTER'⁵⁰ using rotating magnetic field gradients in conjunction with noise-modulated rf pulses. In general, flat saturation is very difficult to achieve.⁵¹ This particularly holds true for water-suppressed proton NMR studies where even minor signal contributions from outside the VOI may lead to substantial spectral contamination when integrated over the

entire volume. Spatial presaturation therefore seems to be restricted to applications in NMR imaging, e.g. to avoid aliasing by outer volume/plane saturation or to manipulate directional blood flow in angiography or cardiac applications.

Another category of method is formed by localization sequences combining two or more basic techniques such as DIGGER with SPACE,⁵² VSE (or SPARS) with spin echo rf excitation,⁵³ 1D-ISIS with PRESS,⁵⁴ and spin echo rf excitation with STEAM.⁵⁵ In addition, new rf pulse designs and foreseeable improvements in magnetic field gradient performance with regard to strength, speed, and accessible waveforms promise multidimensionally selective excitation by just one rf pulse. Preliminary results have been reported for 2D selective^{56,57} and even 3D selective rf pulses⁵⁸ as well as for special hardware developments such as radial gradient coils.⁵⁹ In spoiling unwanted magnetization from planar excitations by rotating gradients, the latter approaches bear similarities to spatially selective saturation techniques. Again, current results underline some potential in NMR imaging, whereas applications for localized proton NMR spectroscopy still suffer contamination problems.

Finally, mixed forms of NMR spectroscopy and imaging have been proposed that achieve spectral localization with use of optimized point spread functions reflecting the shape of a desired VOI. For example, the *spectral localization with optimal pointspread function* (SLOOP)⁶⁰ as a generalization of the spectral localization by *imaging* (SLIM)⁶¹ results in a single voxel spectrum from an arbitrarily shaped VOI by means of a CSI acquisition with modulated phase-encoding gradients, i.e. by matched numbers of transients per gradient step. The approach is analogous to Fourier series windowing techniques¹⁷⁻¹⁹ that allow focusing of a spectroscopic image in the rotating frame.

Figure 8 Localized proton NMR spectra of parietal white (top) and gray matter (bottom) of a normal subject obtained using a short echo time STEAM sequence under fully relaxed conditions. Parameters: 2.0 T, VOI $20 \times 30 \times 20 \text{ mm}^3$ (white matter) and $20 \times 30 \times 30 \text{ mm}^3$ (gray matter), $TR/TE/TM = 6000/20/30 \text{ ms}$, 64 transients. Resonances are due to *N*-acetylaspargate (NAA), *N*-acetylaspargylglutamate (NAAG), glutamate (Glu), glutamine (Gln), aspartate (Asp), phosphocreatine and creatine (Cr), choline-containing compounds (Cho), glucose (Glc), *scyllo*-inositol (*scyllo*-Ins) and *myo*-inositol (*myo*-Ins). Chemical shifts are given in parts per million (ppm) and referenced to 2.01 ppm for the CH_3 group of NAA

3 CHARACTERISTICS OF PRESS AND STEAM

Since both PRESS and STEAM sequences excite rf refocused echoes with use of three rf pulses, respective signals are sensitive to modulation by homonuclear spin-spin couplings or lead to the evolution of multiple quantum coherences. These effects are not seen with single pulse FID acquisitions unless surface coil or ISIS techniques are extended by appropriate excitation sequences.⁶² In addition, gradient-localized sequences are subject to motion-induced amplitude and phase errors that either ought to be minimized or may be exploited for motion editing and chemically specific diffusion measurements. Some of these characteristics are discussed in the following sections.

Common properties are also due to the fact that single voxel proton NMR techniques primarily focus on studies of the central nervous system. Such applications are motivated by the

importance and uniqueness of a noninvasive access to cerebral metabolism and its sensitivity to pathologic alterations in disease states of the brain ranging from neoplasms and stroke to psychiatric diseases and inborn errors of metabolism. In addition, proton NMR of the living brain is facilitated by advantageous tissue properties not found in other organ systems such as small variability of magnetic susceptibilities, metabolites with long T_2 relaxation times, and minimum motions.

For human applications the minimum accessible VOI for any of the localization techniques discussed is of the order of 1 mL (e.g. $10 \times 10 \times 10 \text{ mm}^3$). This estimate is based on the following assumptions: (i) a noninvasive approach with use of a circumscribing head coil, (ii) a reasonable measuring time of only a few minutes, and (iii) adequate spectral S/N. Obviously, VOI dimensions of several millimeters result in spectra comprising signals from both neural and glial structures as well as from vascular compartments and/or cerebrospinal fluid. Considerable improvements in spatial resolution will only be possible by interventional procedures using miniaturized rf coils attached to catheters.

3.1 Spin-Spin Coupling

Figure 9 shows the effect of J modulation on spin echo proton NMR spectra of ethanol as a function of echo time TE . A spin-spin coupling constant of $J = 7 \text{ Hz}$ and a chemical shift difference of $\delta = 245 \text{ Hz}$ (2.45 ppm) result in weak coupling of the methylene quartet and methyl triplet even at the low field strength of 2.35 T. Refocusing of the triplet occurs at $TE = 1/J$ or 143 ms (inversion of quartet), while both the triplet and the quartet refocus at $TE = 2/J$ or 286 ms. The central triplet resonance is not modulated due to the absence of a differential precession frequency and the well-known rephasing of resonance offsets (chemical shifts) by rf echoes.

Doublet resonances refocus at $TE = 1/J$, as frequently observed in vivo for the lactate methyl doublet in PRESS spectra of patients with cerebral disorders. This finding is in contrast to corresponding J modulation effects in STEAM spectra since stimulated echoes exhibit modulation frequencies of only half the value of those in spin echo sequences. Accordingly, lactate doublet resonances only refocus at $TE = 2/J$ and integer multiples thereof. Applications of echo spectroscopy to coupled spin systems have been discussed by several authors for PRESS,⁶³ STEAM,⁶⁴ and both localization sequences.^{65,66} In principle, it is even possible to extend these sequences to localized 2D NMR spectroscopy as has been demonstrated for a 2D J -resolved version of STEAM.⁶⁷

With the prominent exceptions of lactate, alanine, and ethanol, most homonuclear proton interactions lead to strong coupling ($J/\delta \geq 0.1$) at low field strengths and therefore give rise to marked multiplet distortions. Such resonance patterns also deviate severely from the modulation behavior of weakly coupled spin systems. In particular, the intensities of strongly coupled multiplets tend to fade out with increasing echo time rather than to rephase at selected echo times. In practical terms it therefore turns out to be best to minimize J modulation by using short echo times and STEAM sequences. A typical example is shown in Figure 10 for the case of *myo*-Ins. The complex multiplet pattern at 7.0 T [Figure 10(a)] is simplified to two major resonances at 3.56 ppm and 4.06 ppm [Figure

Figure 9 Proton NMR spectra of ethanol obtained using a spin echo sequence without spatial localization as a function of echo time ranging from $TE = 20$ – 320 ms (2.35 T). Modulation of the weakly coupled ($J/\delta = 0.03 \ll 1$) methyl triplet (1.20 ppm) and methylene quartet (3.70 ppm) occur with a period of $1/J = 143$ ms (outer triplet resonances) and $2/J = 286$ ms (central quartet resonances). The homonuclear spin–spin coupling constant is $J = 7.0$ Hz (Courtesy of T. Michaelis)

10(b)], whereas the true singlet resonance from the six protons of *scyllo*-Ins at 3.35 ppm remains unaffected. High levels of *myo*-Ins, *scyllo*-Ins, and Cho in white matter of a patient with a mitochondrial enzyme deficiency indicate enhanced membrane turnover and/or gliosis [Figure 10(c)]. The concomitant reduction of NAA and glutamate provides evidence for a loss of vital neuroaxonal tissue.

3.2 Multiple Quantum Effects

In addition to J modulation, stimulated echoes may be affected by the intermediate evolution of multiple quantum coherences during TM (**Multiple Quantum Coherence Imaging**). For example, when using an echo time of $TE = 1/J$ such as to provide antiphase magnetization for a doublet at the end of the first $TE/2$ interval, i.e. $TE/2 = 1/(2J)$, then application of the second 90° rf pulse creates zero-quantum and double-quantum coherences that evolve during the middle interval TM . The final read pulse converts multiple quantum coherences into detectable transverse magnetization and causes an amplitude modulation of the resulting STE signal in correspondence to the phase of the coherence acquired during TM . Assuming gradient switches as for the STEAM sequence shown in Figure 7 where gradients are balanced to refocus single quantum magnetizations of static spins, double quantum coherences become automatically dephased as their precession frequencies correspond to the *sum* of chemical shifts of coupled resonances, i.e. about twice the precession frequencies of transverse magnetizations. Of course, on the one hand, adjustment of gradient refocusing according to multiple quantum order provides a simple means for order selection.⁶⁸ On the other hand, zero quantum coherences survive any gradient spoiling since their

precession frequencies represent the chemical shift *difference* of coupled spins and therefore are completely independent of resonance offsets and magnetic field inhomogeneities.

The effect of zero quantum modulation as a function of TM is demonstrated in Figure 11 for localized STEAM spectra of an aqueous solution of lactate. The TM interval was incremented in steps of 0.5 ms while holding the echo time constant at $TE/2 = 1/(2J) = 68$ ms. The observed zero quantum modulation of the methyl doublet (1.33 ppm) weakly coupled to the methine quartet (4.12 ppm, $J = 7.1$ Hz) refers to the chemical shift difference of 180 Hz at 1.5 T. It is apparent that subtraction of inverted spectra, e.g. at $TM = 27$ ms and 30 ms, would result in twice the lactate methyl doublet while eliminating all non-coupled spins as well as coupled spins with other chemical shift differences, i.e. zero quantum modulation frequencies. The approach clearly indicates potential for *in vivo* lactate editing⁶⁹ in the presence of strong overlap with lipid signals as in skeletal muscle and kidney. Refinements of the basic technique include 2D zero-quantum and double-quantum spectroscopy,^{70,71} considerations of strong coupling,⁷² and most importantly the design of single-shot multiple quantum filters for STEAM localization sequences to overcome the motion sensitivity of subtraction techniques or phase cycling schemes.^{73,74}

In PRESS sequences 180° rf pulses with imperfect slice profiles subject a part of the magnetization to a stimulated echo sequence. Thus, depending on the actual echo times TE_1 and TE_2 and the homonuclear spin–spin couplings involved, PRESS sequences may also lead to multiple quantum modulation. Excitation of respective coherences is best avoided by not creating antiphase magnetization at the time of the second rf pulse, which requires the first half-echo interval $TE_1/2$ in PRESS and $TE/2$ in STEAM to be as short as possible. This

Figure 10 Proton NMR spectra of inositols (Ins) at different field strengths. (a) FID spectrum (7.0 T, $TR = 10\,000$ ms) of a 1:18 mixture of *scyllo*-Ins (singlet at 3.35 ppm) and *myo*-Ins exhibiting a distorted triplet centered at 3.28 ppm, strongly coupled multiplets at 3.5–3.7 ppm, and a distorted triplet at 4.06 ppm (not shown). (b) Localized STEAM spectrum of a 1:12:2 mixture of *scyllo*-Ins, *myo*-Ins, and glucose (Glc) line broadened to mimic in vivo conditions (2.0 T, VOI $20 \times 20 \times 20$ mm³, $TR/TE/TM = 6000/20/30$ ms, 32 transients, acetate reference). (c) Localized STEAM spectrum of left frontoparietal white matter of a patient with Leigh's disease (2.0 T, VOI $16 \times 16 \times 16$ mm³, $TR/TE/TM = 3000/20/30$ ms, 128 transients). (Reproduced by permission of Wiley from Michaelis et al.⁴²)

allows arbitrary echo times TE_2 in PRESS and middle intervals TM in STEAM. A theoretical and experimental comparison of STEAM and PRESS sequences has addressed a number of properties including homonuclear coupling,⁷⁵ minimum attainable TE , slice profiles, and motion/diffusion.⁷⁵

3.3 Flow and Motion

In close analogy to NMR imaging, gradient-localized echo spectroscopy suffers from chemical shift artifacts in localization

Figure 11 Localized proton NMR spectra of an aqueous solution of 100 mM lactate obtained using a STEAM sequence with a middle interval TM ranging from 27 to 33 ms. Other parameters: 1.5 T, VOI $40 \times 40 \times 40$ mm³, $TR/TE = 3000/135$ ms, 4 transients. Antiphase magnetization components at $TE/2 = 1/(2J)$ lead to multiple quantum coherences that evolve during TM . Elimination of all higher orders by magnetic field gradients as in Figure 7 results in exclusive zero quantum modulation of the methyl doublet (1.33 ppm) weakly coupled to the methine quartet (4.12 ppm, $J = 7.1$ Hz). The modulation period reflects the chemical shift difference of 180 Hz at 1.5 T

acuity, i.e. metabolite-specific positional displacements, and signal loss due to amplitude and phase changes associated with macroscopic and microscopic motions (**Whole Body Magnetic Resonance Angiography; Pulsatility Artifacts Due to Blood Flow and Tissue Motion and Their Control; Time-of-Flight Method of MRA; Phase Contrast MRA**). For proton NMR at field strengths of 1.5–2.0 T chemical shift displacements can be overcome by strong magnetic field gradients that reduce the spatial equivalents of chemically induced frequency differences to a submillimeter scale. If residual eddy currents associated with gradient switching lead to spectral distortions, then sufficient decline of frequency fluctuations prior to data acquisition is only achieved by prolonged echo times. In general, phase distortions of spectroscopic time-domain data may be corrected with use of a reference scan.⁷⁶

Flow effects manifest themselves in two different ways: (i) inflow/outflow of spins carrying longitudinal magnetization, and (ii) motion-induced phase errors that reflect the sensitivity of transverse magnetizations to positional displacements in magnetic field gradients with a component along the flow direction. In localized NMR spectroscopy phase changes within the VOI result in partial cancelation of individual magnetization components and thus incomplete refocusing of SE or STE signals. This particularly holds true for large VOI sizes and at long echo times. In addition, overall phase differences from scan to scan may lead to considerable signal attenuation rather than to signal accumulation during data averaging. This observation may be easily verified since the desired S/N improvement will be less than the expected factor of $\sqrt{n}$, with n the number of acquisitions.

Figure 12 (Top) Long echo time STEAM localization sequence with first-order motion-rephasing gradients in all three directions. (Bottom) Localized proton NMR spectra of tap water flowing in a glass tube of 5 cm diameter at different velocities $v = 0, 0.8, 1.3, 2.0$, and 2.9 mm s^{-1} . The spectra were obtained using STEAM sequences in the absence (left) and presence (right) of a velocity-rephasing gradient waveform along the principal flow direction. Other parameters: 2.35 T, VOI $13 \times 13 \times 13 \text{ mm}^3$, $TR/TE/TM = 2000/270/100 \text{ ms}$, 32 transients. (Reproduced by permission of Academic Press from Gyngell et al.⁷⁷)

Figure 12 demonstrates both the amplitude and the phase effect of flowing water on long echo time localized proton NMR spectra obtained with and without velocity compensated gradient waveforms.⁷⁷ Without rephasing, even very small flow velocities of the order of 1 mm s^{-1} cause substantial signal loss (bottom left). Velocity compensation not only eliminates such phase errors and associated signal losses, but also benefits from the inflow effect of unsaturated spins from outside the VOI when using short TR values. A corresponding signal increase is seen at a velocity of 1.3 mm s^{-1} as spectra were acquired under conditions of partial saturation (bottom right).

Irreversible signal loss due to turbulent flow becomes dominant at even higher flow velocities (here at $\geq 2 \text{ mm s}^{-1}$).

In theory, PRESS sequences are less sensitive to motion than STEAM sequences. This is due to the gradient symmetry normally employed for the two slice-selective 180° rf pulses and thus a benefit from the rephasing properties of the secondary SE ('even echo rephasing'). However, for both sequences the best strategy emerges from avoiding flow/motion-induced phase errors with use of short echo times. In special circumstances, flowing spins may be exploited for motion editing. Discrimination of stationary metabolite signals from flowing

metabolites is a common problem in phosphorus spectroscopy of the heart where phosphate resonances from 2,3-diphosphoglycerate in blood within the cardiac chambers contribute to phosphorus spectra of myocardial tissue.⁷⁸ Further applications stem from elimination of resonance signals from flowing liquids used for temperature control in high-resolution NMR. This also holds true for studies of cell suspensions where contamination with substrates from the perfusate may be completely avoided by motion-encoding gradient pairs.⁷⁹

3.4 Diffusion

NMR measurements of molecular self-diffusion coefficients in vivo provide insight into cellular dynamics and give hints as to intra- and extracellular structural organization (*Anisotropically Restricted Diffusion in MRI: Methods and Applications of Diffusion MRI*). While diffusion-weighted NMR imaging of water protons is unable to discriminate between multiple compartments, diffusion-weighted water-suppressed spectroscopy in most cases reflects intracellular metabolite mobility. Such studies may be even more specific since metabolites such as NAA and *myo*-Ins have been found to be exclusively located in neuronal and glial cells, respectively.

The most suitable localization sequence for in vivo diffusion weighting is STEAM. It allows for long diffusion times Δ without detrimental effects due to strong T_2 attenuation in systems with $T_2 \ll T_1$. Thus, variable diffusion times (e.g. different TM intervals) may be used to study the influence of restricted diffusion when dephasing and rephasing parts of the diffusion gradient pair are separated into the first and second $TE/2$ intervals. On the other hand, to determine the free diffusion coefficient in vivo and to minimize encoding of competitive motions such as flow, diffusion weighting is best accomplished by the incorporation of a bipolar self-balanced gradient of duration δ and effective separation Δ into one of the $TE/2$ intervals of the STEAM sequence. While this strategy compensates for motion-induced phase errors as long as pertinent motions exhibit constant velocity, a further reduction of the flow/motion sensitivity of diffusion-weighted sequences is achieved by respiratory triggering and/or scan-to-scan phase alignment using postacquisition correction schemes.

Figure 13 shows diffusion-weighted localized proton NMR spectra of rat brain obtained using bipolar diffusion gradients during both $TE/2$ intervals to yield short diffusion times of $\Delta = \delta = 25$ ms at an echo time of $TE = 120$ ms.⁸⁰ The acquisition of spectra with metabolite signal intensities $S(b)$ as a function of diffusion weighting factor b allows the calculation of molecular self-diffusion coefficients D from the signal attenuation according to

$$\ln(S/S_0) = -Db \quad (9)$$

with

$$b = \gamma^2(\Delta - \delta/3)\delta^2 G^2 \quad (10)$$

and G the diffusion gradient strength. Since metabolite diffusion coefficients in vivo can only be measured in the presence of residual unavoidable/uncorrectable motions, values are expressed as apparent diffusion coefficients (ADC).

The ADC value of $0.27 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ found for NAA, Cr, and Cho in rat brain is about a factor of three smaller than

Figure 13 Diffusion-weighted localized proton NMR spectra of rat brain in vivo obtained using a STEAM sequence with bipolar diffusion gradients G in each $TE/2$ interval ($\Delta = \delta = 25$ ms). Other parameters: 2.35 T, VOI $5 \times 5 \times 5 \text{ mm}^3$, $TR/TE/TM = 3000/120/30$ ms, 128 transients triggered to respiration. Spectra with increasing diffusion weighting factor b according to equation (10) are shown from bottom to top (150, 1520, and 3040 s mm^{-2}). The orientation of the diffusion gradient was along the long axis of the animal. (Reproduced by permission of Williams and Wilkins from Merboldt et al.⁸⁰)

the water proton ADC of $0.75 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$. In human subjects an ADC value of $0.65 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ was obtained for water protons, while values of 0.18 , 0.15 , and $0.13 \times 10^{-3} \text{ mm}^2 \text{ s}^{-1}$ were reported for NAA, Cr, and Cho, respectively.⁸¹ The finding of smaller metabolite ADC values in human brain compared with rat brain is most likely to be due to the use of a long diffusion time of $\Delta > 200$ ms in the human study that reduces the ADC by the influence of restricted diffusion.

Table 1 Absolute concentrations (mM) of major metabolites in human parieto-occipital white and parietal gray matter in vivo as obtained from fully relaxed ($TR = 6000$ ms) short echo time ($TE = 20$ ms) localized proton NMR spectra (STEAM) of young healthy adults (age 27 ± 4 years).⁸² The values have been determined without user interference using a fully automated spectral evaluation program⁸³ and a library of localized model metabolite spectra calibrated with known concentrations.⁸⁴ VOI concentrations are given without corrections for partial volume effects and T_2 relaxation differences between in vitro and in vivo conditions.

	White matter ($n = 61$)	Gray matter ($n = 45$)
NAA + NAAG	8.2 ± 0.7	9.1 ± 0.7
NAA	6.1 ± 0.7	8.9 ± 0.8
NAAG	2.1 ± 0.7	0.3 ± 0.4
Cr + PCr	4.9 ± 0.6	6.5 ± 0.5
Cho	1.6 ± 0.2	1.2 ± 0.1
myo-Ins	4.2 ± 0.7	4.4 ± 0.6
Glu	5.8 ± 1.2	8.8 ± 1.1
Gln	1.8 ± 1.2	4.1 ± 1.3

Despite current limitations with regard to gradient strength and eddy current performance, diffusion spectroscopy is an active area of research. This is largely due to expectations that cell-specific information will contribute to the understanding of pathophysiologic events associated with stroke. In contrast to water diffusion NMR imaging, studies of intracellular metabolites may clarify the nature of the reduced water ADC observed shortly after ischemia as well as its subsequent rise to larger than normal values within 5–7 days after stroke.

4 SINGLE VOXEL LOCALIZATION OR CHEMICAL SHIFT IMAGING?

Biological NMR covers a wide range of diverse methods and applications. Thus, the absence of a ‘single best’ technique for a complex field such as in vivo NMR spectroscopy is not surprising. Instead, different problems will require different solutions and specific applications should ask for problem-oriented decisions as to which strategy to employ. For example, single voxel localization and CSI techniques are complementary with regard to temporal resolution and volume coverage. While CSI provides simultaneous access to the spatial distribution of metabolites in one, two, or three dimensions, the strength of a single voxel spectrum arises from a more detailed and more easily quantifiable metabolic picture, as well as from its speed. These factors are often beneficial to studies of cerebral metabolism by proton NMR spectroscopy, whereas the poor sensitivity and long measuring time of localized phosphorus NMR spectroscopy are more efficiently compensated for by CSI techniques with improved S/N per unit measuring time.

Accurate definition of the spatial origin of a spectrum is a prerequisite for its biochemical (and medical) interpretation. Single voxel techniques achieve this goal by direct slice-selective excitation of the VOI, whereas the spatial characteristics of a voxel spectrum from CSI reflect the point-spread function associated with discrete 1D, 2D, or 3D Fourier transformation. Since only small numbers of 8–32 phase-encoding steps per

dimension are acquired due to time constraints of in vivo studies, the resulting sidelobes may cause significant signal contamination. Typically, a 2D CSI experiment with a 32×32 matrix and a repetition time $TR = 2000$ ms already leads to a measuring time of 34 min which is often beyond patient tolerance and hampered by motion artifacts.

Single-shot localization techniques such as PRESS and STEAM allow direct ‘shimming’ of the VOI. Good homogeneity improves the spectral quality in two respects: firstly, in terms of chemical shift resolution, and secondly, in terms of contrast-to-noise since the relevant parameter for detectability of a resonance is its peak-to-noise ratio rather than the signal strength as given by the resonance area. The residual linewidth of in vivo proton NMR spectra of human brain does not reflect spin–spin relaxation, but is determined by microscopic susceptibility differences resulting in inhomogeneous broadening. Another benefit from homogeneity and local parameter optimization is the excellent water suppression obtainable even for short echo times.

A most attractive aspect of single voxel proton NMR is the short measuring time of only a few minutes that may be exploited for several purposes. For example, a reliable quantitation of absolute metabolite concentrations without the need for saturation corrections may be accomplished by using long repetition times for fully relaxed acquisitions. Thus, typical recordings of localized proton NMR spectra of human brain (headcoil, 1–20 mL VOI) result in a measuring time of about 6 min assuming 64 transients with a repetition time $TR = 6000$ ms. The corresponding measuring time for the aforementioned 32×32 2D CSI experiment yields 102 min. Table 1 summarizes VOI concentrations of major metabolites in human brain in vivo from fully relaxed proton NMR spectra of white and gray matter.⁸² The analysis was based on fully automated spectral evaluation⁸³ that takes advantage of a library of localized spectra from calibrated model metabolite solutions.⁸⁴

Single voxel spectroscopy studies also provide immediate access to results without extensive postexamination processing as required for CSI. Control of spectra during the session improves the quality of patient studies by interactive decisions and avoids repeat studies. Most importantly, however, a temporal resolution of minutes allows monitoring of the time course of a physiological alteration or metabolic turnover via sequential acquisitions. An illustrative example is the uptake of ethanol after oral consumption of alcohol as shown in Figure 14 where proton NMR spectra from parietal gray matter reveal the methyl triplet signal only 12 min (top trace) after drinking.⁸⁵ The bottom part of Figure 14 shows the time course of the ethanol concentration in gray matter. Subsequent to a rapid increase, maximal tissue concentrations (central trace) were reached after 40–75 min (different subjects) followed by a slow decrease. Further examples of dynamic NMR spectroscopy deal with localized studies of glucose uptake and homeostasis,^{28,85} glucose and lactate levels during physiologic stimulation,^{25,86} and functional alterations of water proton signal strength and linewidth during brain activation.⁸⁷

In conclusion, the selection of a localization technique should only depend on the question to be answered. In this respect, theoretical and experimental comparisons may be helpful in evaluating basic physical properties, but are of limited usefulness for a generalized judgement of relative merits. The ultimate criterion is of course given by the condition that the

Figure 14 Uptake of ethanol (Eth) in parietal gray matter of a young healthy subject after drinking 1 mL of ethanol/kg body weight within a period of 5 min. (Upper traces) Localized proton NMR spectra reveal the presence of the methylene-coupled methyl triplet of brain ethanol at 1.20 ppm, 12 min and 61 min after drinking, respectively. Parameters: 2.0 T, VOI $16 \times 30 \times 30 \text{ mm}^3$, STEAM, $TR/TE/TM = 3000/20/30 \text{ ms}$, 128 transients. (Bottom graph) Time course of ethanol and creatine levels in gray matter as evaluated by LCModel⁸³ in comparison with blood plasma ethanol values (right scale). Tissue concentrations are not corrected for T_1 saturation, partial volume effects, and differential T_2 attenuation between in vivo and in vitro conditions. (Reproduced by permission of Plenum Press from Frahm⁸⁵)

results of a localized NMR spectroscopy examination must be independent of the method chosen. Otherwise, in vivo NMR will not justify its potential as a unique noninvasive tool for both metabolic research and medical decision-making.

1 INTRODUCTION

In vivo ^{31}P MRS has become an established research tool for studying metabolism in both animals and humans. Up to seven peaks can be identified in tissues (more if proton decoupling is employed). For muscle and brain tissue these peaks correspond to: phosphomonoesters (PME), inorganic phosphate (Pi), phosphodiester (PDE), phosphocreatine (PCr), and the γ -, α -, and β -phosphates of adenosine 5'-triphosphate (ATP). The contribution of each peak to the total spectrum is expressed by calculating the area under each of the peaks and expressing the result as a percentage (mol%) of the total phosphate signal. The energetic state of brain tissue may be characterized by the PCr/Pi ratio, which is an approximate measure of the phosphorylation potential when the creatine kinase reaction is at equilibrium, and which decreases in situations of insufficient energy production. In vivo ^{31}P MRS also provides a non-invasive measure of pH by utilizing the dependence of the chemical shift of Pi on pH.¹ In addition, the relative chemical shifts of Pi, PCr, γ -, α -, and β -ATP can be used to estimate the concentration of free Mg^{2+} ions,² which play a role in membrane stability and are involved in phosphoryl transfer reactions during glycolysis. Finally, the presence of ATP is ubiquitous in all living tissues, and its depletion presages serious cell injury or, eventually, cell death. Therefore, in vivo ^{31}P MRS provides a wealth of information that is unobtainable by other noninvasive techniques.

The primary technological problem for in vivo ^{31}P MRS is a lack of sensitivity caused by the low metabolic concentrations of NMR-visible phosphorus metabolites of biological interest. The experimental complexity and the logistics of applying long NMR experimental procedures to study human disease have limited the widespread application of in vivo NMR spectroscopy in clinical diagnostic studies. It is, therefore, of utmost importance that the NMR spectrum is acquired with optimum sensitivity in order to minimize the experimental duration.

Interpretation of spatially localized in vivo ^{31}P NMR spectra depends upon a knowledge of the location and size of the tissue volume investigated in the experiment. Tissue specificity is essential to eliminate signals emanating from tissues of different type or metabolic status. For instance, contamination of the ^{31}P spectrum from brain tissue can arise from the scalp and neck muscles which are rich in high-energy phosphates, especially PCr, thereby giving a disproportionately intense contribution to the spectrum. It is the goal of any localization method to facilitate the acquisition of in vivo NMR spectra by minimizing contamination from undesired tissue volumes, and maximizing the S/N ratio to minimize experimental duration. In addition, many of the ^{31}P resonances of interest have short T_2 values, thus requiring an excitation and localization scheme which minimizes signal losses due to T_2 relaxation.

2 TECHNIQUES

2.1 Surface Coil and Related Methods

The first spatially localized in vivo ^{31}P MRS experiments were performed using surface coils,³ which consist of a loop of wire placed in close proximity to the subject, and positioned so that a major component of the B_1 field of the coil is perpendicular to the B_0 field. The coils can be used for both transmission of the rf pulses and signal reception. Most of the measured signal originates from an approximately hemispherical volume of tissue of equal radius to the coil. However, the spatial sensitivity of surface coils is inherently inhomogeneous and decreases rapidly with distance from the coil. The spatial weighting of the signal in an experiment is a function of the rf pulse length and repetition time, so the spatial response pattern is both irregularly shaped in space and of variable sensitivity as a function of position. For these reasons, surface coils are often used in combination with other methods.

Although no longer being used, Topical Magnetic Resonance (TMR) provided the first three-dimensional spectroscopic localization method by generating a uniform B_0 field over a limited spatial region, with a very inhomogeneous field in surrounding regions.⁴ Moreover, the TMR method could be used with surface coils for improved localization. However, the spatial localization achieved by the combined method is not sharply defined, having edges which are quite diffuse. Another major disadvantage is that the region of interest is centrally located within the magnet bore assembly, having been generated by the combination of powerful Z^2 and Z^4 shim coils, and cannot be easily moved.

'Depth' pulse methods provide another approach to improved localization over that afforded by a single surface coil.⁵ In brief, depth pulse methods rely on phase cycling with multiple acquisitions to obtain signals from regions experiencing a particular value of B_1 field strength. Other, analogous, surface coil methods which retain signals from a region within a limited range of B_1 field have also been demonstrated.⁶⁻⁹ However, full, three-dimensional localization requires the use of two surface coils of differing sizes.¹⁰

In the middle 1980s, the availability of pulsed magnetic field gradients enabled new classes of localization experiments to be developed; namely, methods relying on the application of frequency selective rf pulses in the presence of magnetic field

gradients. The first of these methods, entitled Depth Resolved Surface coil Spectroscopy, provided for observation of a plane of material parallel to the plane of the coil.¹¹ Another variation of the method enabled multiple parallel slices to be simultaneously investigated.¹² A disadvantage of the method is that the selected volume is a flat disk which is not conveniently shaped for the investigation of many organs. Also, T_2 relaxation occurs during the slice selective refocussing period following the 90° rf pulse, leading to some degree of spectral distortion.

All surface coil techniques benefit from the inherent high sensitivity of signal reception from material close to the coil. However, all of the above methods suffer the disadvantage that the localized region is fixed in space, and the subject must be positioned appropriately with respect to the coil(s).

2.2 Three-Dimensional Selective Excitation Methods

The combination of three selective pulses in conjunction with pulsed magnetic field gradients applied along orthogonal axes, can be used to excite a volume of material which is defined at the intersection of all three planes. Many techniques use this principle; however, the exact nature of the spatial definition process falls into three general categories:

1. Outer volume suppression methods which selectively nutate spins in unwanted regions of the sample into the transverse plane, where the signal is dephased by applied gradients. The desired signal, which has been preserved along the longitudinal axis, is then read out using a 90° rf pulse. Examples of this principle are: Volume Selective Excitation,¹³ Spatially Resolved Spectroscopy,¹⁴ localization of unaffected spins in NMR imaging and spectroscopy (LOCUS),¹⁵ 'SPACE',¹⁶ and 'DIGGER'.¹⁷
2. Direct excitation methods in which the MR signal of interest spends some portion of the experiment evolving in the transverse plane prior to forming an echo in the signal acquisition period. Examples are Pixel-Resolved Spectroscopy (PRESS),^{18,19} which uses a 90°–180°–180° selective pulse sequence and acquires a spin echo, and Stimulated Echo Acquisition Method (STEAM)²⁰ which uses a 90°–90°–90° sequence and acquires a stimulated echo.
3. Cancellation methods in which the entire sample volume is excited, but the signal has been previously prepared using 180° selective pulses so that spatial information is encoded in the longitudinal magnetization prior to signal acquisition, and unwanted signal is canceled following combination of the signal from a series of experiments. An example of this principle is Image Selected In vivo Spectroscopy (ISIS).²¹

The advantages of all these methods is that because of the use of selective pulses in combination with field gradients, the size and position of the selected volume can be directly related to a previously obtained MR image. The selected volume is regularly shaped (usually a cube or rhomboid), and the size and position can be easily varied with reference to an MR image by modification of the selective pulse carrier frequency and applied gradients.

A disadvantage shared by all localization schemes which employ selective excitation is the presence of a chemical shift related spatial localization error.²¹ When nuclei with different chemical shifts are examined, the associated differences in

NMR resonant frequency cause an erroneous displacement of the selected region for each chemical shift value. The displacement error, ΔX is given by the equation:

$$\Delta X = \frac{\sigma B_0}{G_x} \quad (1)$$

where σ is the chemical shift value relative to a suitable reference peak, B_0 is the main magnetic field strength, and G_x is the gradient strength applied in the x direction during the spatial localization procedure. This problem can be minimized by using large magnetic field gradients for spatial localization since ΔX is inversely proportional to G_x . At a field strength of 2 T, a localized ^{31}P spectrum (σ range ± 12.5 ppm) obtained with a field gradient of 1 G cm⁻¹ has associated spatial localization errors of ± 2.5 mm irrespective of the size of the selected region. The disadvantage of using higher gradient strengths is an increase in the rf power required to select a region of fixed size, since the bandwidth of the rf selective excitation pulse must be increased by reducing the pulse length. The rf power is ultimately limited by the rf power amplifier.

Techniques in category (1) are difficult to implement primarily because they are susceptible to signal error arising from volumes of tissue where the NMR signal has not been effectively destroyed. This can be caused by rf field inhomogeneity, insufficient rf power, or even spin-lattice relaxation during the experiment. Without exception all the techniques in category (1) benefit from phase cycling in a series of experiments to cancel the unwanted signal. Phase cycling can sometimes be achieved in two experiments; however, the most general and accurate cancellation is only achieved in eight experiments (two experiments per spatial axis).

For in vivo ^{31}P MRS, techniques in category (2) suffer from the disadvantage of signal loss due to T_2 decay. Thus, these methods have found limited application in ^{31}P studies,²² although they are widely used for in vivo ^1H MRS studies.

The disadvantage of category (3) methods and specifically ISIS, is that large NMR signals often have to be canceled in order to determine the residual signal from a small selected volume surrounded by a large mass of tissue. Such cancellation is subject to errors caused by system instability, or by subject movement. The solution is to minimize the large unwanted signal components prior to application of the ISIS method, using methods which are similar in principle to the techniques in category (1).²³ Since ISIS is, at present, the most widely used method for ^{31}P MRS, it is now described in greater detail.

The ISIS technique uses selective excitation in combination with the differencing of NMR signals from a sequence of eight experiments to select a rectangular-shaped volume of tissue for spectroscopic analysis. Upon combination of the free induction decays (FIDs) from the eight ISIS experiments, signal from the desired volume adds, whereas signals from all external regions cancel. The method relies on the principle of selective inversion of the spin population prior to data acquisition. The selective inversion pulses (180° pulses) cause inversion of longitudinal magnetization in selected slices of the sample using frequency selective rf excitation pulses in combination with applied field gradients. The selective pulses are applied in sequence along the X , Y , and Z axes. The experimental sequence is illustrated in Figure 1, and the rf selective inversion pulses either applied, or withheld, in a sequence of eight experiments are shown in the accompanying table. A delay

Figure 1 Pulse sequence used for the ISIS technique, and table indicating the order of RF pulse application during the eight experiment sequence. The addition or subtraction of relevant signals is indicated by a + or - sign

period follows application of each sequence to allow for spin-lattice relaxation.

The size of the selected region can be varied along any dimension by altering the excitation profile width of the respective rf pulse or the gradient associated with this rf pulse, thereby defining a rectangular volume. The position of the volume can be altered by adjustment of the individual frequency offset of each of the rf selective pulses. The size and position of the volume may thus be selected by reference to (and visualization with respect to) standard ^1H MR images of the subject.

For simplicity, the effect of a two-dimensional ISIS sequence on a two-dimensional spatial distribution of NMR spins is depicted in Figure 2. Four experiments are applied and the square array of nine elements represent three spatial regions along each axis. The hatched regions represent volumes which are inverted by ISIS prepulses in each of the four experiments. A double inversion (360° spin flip) is formed at the intersection of the inversion planes in experiment B2 (cross hatched region), and plain boxes do not receive any spin preparation prepulse. Selection of the central volume is achieved by combining the signals from the four experiments in the sequence of $A1 - A2 - B1 + B2$ whereupon all outer volumes correctly cancel. Three-dimensional selection (not depicted) involves extension of the scheme, and requires eight experiments, with the application of up to three selective inversion pulses, as indicated by the table which accompanies Figure 1.

The main advantage of ISIS is that signal readout immediately follows a nonselective 90° excitation pulse. This makes the method particularly useful in the study of MR signals with a short T_2 value, and specifically in the measurement of ^{31}P metabolites. Cancellation of signal outside the selected volume is accurate irrespective of the spin nutation angle experienced during each selective preparation pulse. However, selective 180° rf pulses are desirable since they provide the optimum sensitivity from spins within the ISIS volume. It is also preferable to use adiabatic, selective rf pulses such as the hyperbolic-

secant selective inversion pulse proposed by Silver et al.²⁴ This ensures that material within the ISIS volume contributes fully in each of the eight experiments, and the optimum S/N ratio performance is achieved virtually independent of both the rf field inhomogeneity of the coil and the rf power level applied during each selective pulse. When used with adiabatic inversion pulses, the ISIS technique can be executed very effectively with surface coils to obtain improved signal sensitivity from regions close to the surface of the subject. The experiment can be made completely independent of rf power setting by replacing the 90° readout pulse with a nonselective adiabatic 90° rf pulse. Adiabatic rf pulses are commonly used in the ISIS sequence, even when the rf coil is nominally homogeneous, because they remove the need to calibrate accurately rf nutation angles.

An additional advantage of the ISIS technique is that the rectangular volume may be tilted along any axis by replacing standard Cartesian gradient pulses by mixtures of gradients, e.g. selection along a 45° axis can be achieved by simultaneous application of equal X and Y gradient pulses during the appropriate rf selection period. The ISIS volumes may also be a parallelepiped in shape if the selection gradients are applied along nonorthogonal axes.²⁵ The modified ISIS volume may thus be shaped to fit better within a particular region of interest, thereby increasing S/N performance.

There are several variations in the order in which the ISIS experiments may be applied. These have been devised to (i) allow optimal signal cancellation from undesired regions when there is rf inhomogeneity present and the experimental repetition delay is insufficient for complete spin-lattice (T_1) relaxation, and (ii) reduce signal cancellation errors caused by

Figure 2 Diagrammatic representation of two-dimensional selection using an ISIS sequence of four experiments. The central square represents the region of interest, and is bordered along both x and y spatial dimensions by material that provides undesired signal. Inversion of a slice along x and y dimensions in experiments A2, B1, and B2 is indicated by hatched regions, and the cross hatched region (volume of interest) represents spins which have been inverted twice (e.g. 360° nutation)

subject motion. Matson et al.²⁶ include a 90° rf pulse following signal acquisition to ensure that T_1 relaxation commences from zero magnetization during the experimental delay period, thereby ensuring that longitudinal magnetization reaches the same state prior to each new acquisition. The experiments can then be applied in complete sequences of eight and the whole ISIS experiment is repeated successively in order to perform signal averaging. This makes the sequence less prone to movement errors and may have benefits when studying the torso. For head studies, where patient motion is not of great concern, the standard ISIS experiments may be averaged at each of the eight steps, since errors associated with relaxation will cancel upon final subtraction/coaddition of the data.²¹ The absence of a 90° rf saturation pulse at the end of the signal acquisition period allows spin-lattice relaxation to proceed from the excitation pulse onwards, thus providing improved signal collection efficiency.

The method can be extended to investigate simultaneously two localized volumes centered on a common x axis but separated along the y axis. Three-dimensional ISIS with two selected cubes requires a minimum of 16 different sequences and up to four selective inversion pulses. This variation of the method is of particular use in biomedical studies since it allows simultaneous measurement of an equivalent contralateral region, thus providing an internal reference for biochemical changes in focal disease states. An example is presented in Figure 3, which shows *in vivo* ^{31}P brain spectra obtained from a stroke patient in the stroke-affected region and in the contralateral region for comparison.

The ISIS principle may also be extended to the simultaneous acquisition of multiple (2^n) volumes.²⁷ Since signal averaging is a necessity for *in vivo* ^{31}P spectroscopy, multiple volume spectra can be acquired with no increase in experimental duration compared with a single volume experiment. An extended sequence of selective spin inversion pulses is required in both the Hadamard transform approach²⁸ and the equivalent multicube ISIS method.

3 MEASUREMENT OF METABOLIC CONCENTRATIONS

Although most MRS data have been reported as spectral peak area ratios, quantitative methods have been developed for estimating molar concentrations of metabolites using *in vivo* MRS with single volume localization.^{29,30} The principle requirements for quantitation are (a) to obtain accurate spectral integrals for the metabolite peaks of interest, (b) to determine the spatial sensitivity (B_1 field distribution) of the rf transmitter/receiver coil, (c) to compare with a calibration sample of known concentration, and (d) to determine saturation and relaxation effects (T_1 and T_2) for rapidly repeated rf excitation.

The procedure typically involves measuring a ^{31}P MRS spectrum during each localization experiment from a small sample fixed to the rf coil assembly, or to the subject (e.g. containing hexamethylphosphorus triamide with a peak chemically shifted about 110 ppm downfield from PCr). This signal is used to determine rf pulse lengths, and as a reference to account for variations in coil sensitivity (Q factor) caused by variable loading. Spectral peak areas are then compared with the signal from a calibration phantom containing a known con-

centration of inorganic phosphate, which is measured periodically using the same spatial localization procedure. The formula used to obtain the absolute molar concentrations of metabolites might also take account of differences in the aqueous fraction between samples, (e.g. taking account of cerebrospinal fluid volume in head studies) which requires additional MRI data. The T_1 values for all metabolite resonances must also be known to obtain a saturation correction when the experimental repetition rate is high. A more complete explanation is provided in other articles (see Related Articles).

4 APPLICATIONS

In this section we present a very brief overview of some applications of single voxel whole body ^{31}P MRS in humans, with the intent of providing examples of the kinds of metabolic information available from such ^{31}P MRS studies. Many of the organs and diseases are reported on in much more detail in other chapters (see Related Articles).

4.1 Human Brain and Brain Diseases

The contralateral ^{31}P spectrum in Figure 3 is representative of normal adult brain at 3.0 T, and illustrates prominent ^{31}P resonances as identified in the figure legend. The infant brain is characterized by higher PME levels and somewhat reduced PCr. The broad hump commonly attributed to lipid resonances is less prominent at 3.0 T than at 1.5 T as a consequence of the chemical shift anisotropy relaxation mechanism. With proton decoupling, the PDE resonance splits into separate glycerophosphocholine and other PDE resonances.³¹

Phosphorus-31 MRS single voxel studies have been performed in AIDS or HIV infection, Alzheimer's disease, deep white matter lesions, epilepsy, multiple sclerosis (MS), stroke, and brain tumors. Representative trends of the ^{31}P metabolite concentration for these diseases are indicated in Table 1. Other diseases and conditions studied by ^{31}P MRS include alcoholism (and other drug use), migraines, schizophrenia and other mental disorders, and various pediatric diseases.

4.2 Heart

Although some early single volume ^{31}P MRS studies in human heart have been performed,^{26,32,33} more recent studies have used more elaborate localization methods, including multiple volume methods, to combat the need to obtain very small volumes (particularly for studies of ischemia or infarction) from a moving organ.

4.3 Liver and Kidney

A ^{31}P spectrum of human liver obtained at 1.5 T is shown in Figure 4. The most notable feature, as compared with a brain spectrum, is the lack of PCr. In fact, the absence of PCr is often taken as an indication of lack of contamination from surrounding muscle tissues which contain significant concentrations of PCr. Disease conditions studied in human liver include cancers, alcoholic hepatitis and cirrhosis, and fructose intolerance. Disease typically produces a decrease in ^{31}P

Figure 3 MR images and ^{31}P spectra obtained from a stroke patient at a field strength of 3 T using ISIS. The two regions studied using ^{31}P MRS were investigated simultaneously ($TR = 1.5$ s, number of acquisitions = 768, MRS study completed in 20 min), and incorporate tissue extending from the regions shown in the top slice through to those in the bottom slice (volume of each cube = $3 \times 3 \times 3 \text{ cm}^3$). Peaks correspond to (from left to right) phosphomonoesters (PME), inorganic phosphate (Pi), phosphodiester (PDE), phosphocreatine (PCr) and the γ , α -, and β -phosphates of ATP. The spectrum from stroke-affected tissue (right) should be compared with that from the unaffected contralateral region (left)

metabolites, while fructose intolerance is marked by reduction in ATP following ingestion or administration of fructose.

Few ^{31}P MRS studies of normal kidney have been reported due to the depth of this organ in the body. However, transplanted kidney is typically much closer to the surface and

easier to study. Several groups have made preliminary studies of transplanted kidneys and ^{31}P MRS has the potential to assess transplanted kidney metabolic health, and possibly to assist in analyzing tissue status or pathology following transplantation.

Table 1 Representative Trends of ^{31}P Metabolite Concentration for Various Diseases

Diseases	Observations
Alzheimer's	Ranges from no observable changes to reported increases in PDE and possibly PME.
Deep white matter lesions	Reductions in PME, PDE, and ATP
Epilepsy	Reduced PME, increased Pi, and decreased pH (interictal studies of focal temporal lobe epilepsy)
HIV	Reduced ATP/Pi in AIDS dementia complex
MS	Ranges from no observable changes to decreases in PDE, and reduced PME and Pi (chronic lesions)
Stroke	Reductions in all metabolites; decreased pH in acute phase; increased pH in some chronic infarcts
Tumors	Variable metabolite reductions in PDE and PCr, elevated PME, depending upon tumor type

4.4 Human Muscle

By far the largest number of ^{31}P MRS studies in humans have been performed on muscle, ranging from the study of normal muscle metabolism under various conditions of (and recovery from) exercise, to studies of the alterations of muscle metabolism in various disease states. Under light to moderate exercise, normal muscle displays a fall of PCr and a fall of pH (after an initial slight rise), with maintenance of ATP levels. Alterations of metabolic concentration with work, or under recovery conditions, may be further changed by a variety of diseases, and ^{31}P MRS has proven to be clinically useful in a number of muscle disorders. However, the localization has traditionally been accomplished by the sole use of surface coils.

4.5 Body Tumors

Tumor spectra typically display a high PME, and often reduced PCr compared with the surrounding or normal tissue. Although early studies indicated that ^{31}P MRS might have considerable potential in the assessment of tumor therapy, the investigation of tumors in the body has proved difficult. While some early studies seemed to indicate that reductions in PME

heralded effective therapy, more recent studies have shown that no such simple interpretations generally prevail.

5 CONCLUSION

Single voxel whole body ^{31}P spectroscopy may be performed within acceptable experimental durations in high-field magnet systems. The most commonly used method, ISIS, while not devoid of problems, offers a reasonably robust method of localization. Two cubes may be investigated simultaneously to allow an internal comparison between different regions of biological tissue.

Application of all these single voxel localization methods requires the location of the volume to be chosen from an MR image, which assumes that the operator can either observe a region of abnormality on the image, or can identify the region from clinical symptoms. If the region of metabolic dysfunction is not known, and the contrast provided by MRI is insufficient to identify the region, chemical shift imaging (CSI) offers the advantage that all regions of the sample are investigated to produce a map of each metabolite. The region of interest may then be defined on the basis of metabolic changes following data acquisition. However, CSI methods are generally more time consuming than ISIS, and rapid experimental repetition rates result in distorted spectra which must be corrected for T_1 relaxation for the purposes of quantitation. Both approaches offer advantages and disadvantages in their application to specific studies, and appropriate choice of methodology usually involves a compromise.

Spatial Localization Techniques for Human MRS

David J. Bryant and Glyn A. Coutts

GEC Hirst Research Centre, Borehamwood, Herts, UK

1 INTRODUCTION

The surface receiver coil has received widespread use in the acquisition of in vivo magnetic resonance (MR) spectra.¹⁻³ Its characteristic of high magnetic field (B_1) flux density in close proximity to the coil provides spectra of good signal-to-noise ratio (S/N) and provides a level of spatial localization. Applications involving deep-seated organs and pathology give inferior results through lack of sensitivity and contamination from unwanted surface signals.

A number of techniques have been developed over the years in order to provide flexibility in positioning the regions from which spectroscopic data can be acquired. In this article a general description of the localization methods investigated to date are described. The predominant techniques and their applications now in use are described in the related articles listed at the end. The wide range of techniques involve manipulation of the applied magnetic field B_0 , either by static profiling or by the use of B_0 field gradients, or the use of radiofrequency B_1 field gradients. The choice of localization technique will often be as a result of the availability of specific hardware components. Radiofrequency (rf) techniques are particularly tied to the use of the surface transmit coil. The flexibility of location and size or field-of-view offered by the B_0 field gradient methods places a greater premium on the control of eddy currents, high homogeneity rf coils, and rf pulse design. These additional features are also included in the related articles listed at the end of this article.

2 STATIC FIELD PROFILING

The higher order spatial harmonics of the magnetic field B_0 are designed to limit the size of the homogeneous volume from which high-quality spectra can be obtained. Signals outside and on the periphery of this volume are inhomogeneously broadened and are either absent from the signal or can be removed by postprocessing. Topical magnetic resonance (TMR) has been demonstrated,^{4,5} in conjunction with surface transmit and receive coils, to give high-quality spectra. The homogeneous volume from which the signal is derived is not particularly well-defined and there is very little control over its position and dimensions. Realignment of the patient is required in order to achieve this level of control.

A related approach has been suggested⁶ which employs a surface B_0 field gradient coil that degrades the quality of field

in its close proximity. The nonlinear gradient is pulsed during the first τ interval of a spin echo sequence to ensure that only signals remote from the surface gradient coil contribute to the echo. Irreversible dephasing of surface signals has also been achieved by the use of immobilized ferrite particles with a simple pulse and collect acquisition of the data.⁷ Both of these approaches give a robust method of removing the intense unwanted signals near to an rf surface receive coil.

3 RADIOFREQUENCY (B_1) METHODS

This family of techniques relies upon the use of the surface coil as a transmitter system. The spatial variation in the transverse components of B_1 perpendicular to the static field B_0 can be manipulated to produce spatially constrained spectra. It would not be uncommon for the transmitter and receiver of the rf system to be physically different coils such that localization attributes can be optimized with the transmit coil while the reception qualities are not prejudiced.

The axial components of the B_1 field along the axis of a single current carrying loop are given by:

$$B_1(r) = \frac{\mu_0 i}{2} \cdot \frac{R^2}{(R^2 + r^2)^{3/2}} \quad (1)$$

where μ_0 is the magnetic permeability, i the current in the loop of radius R , and r the position along the axis of the coil. Assuming a square excitation pulse of duration t_p , the transverse magnetization M_{xy} at each point along the axis is proportional to $\sin \theta(r)$, where $\theta(r)$ is the spatially-dependent pulse angle given by $\gamma B_1(r) t_p$ (radians). The sinusoidal dependence of M_{xy} has been exploited in a number of ways to project the region of interest away from the proximity of the coil.

3.1 Depth and Composite Pulses

Analysis of equation (1) demonstrates that a 90° excitation is experienced at $0.77R$ when $B_1(0)$, the field at the center of the coil, is set to 180° . Peak signal is generated at $0.58R$ for a transmit/receive surface coil arrangement where the signal is proportional to $\theta(r) \sin \theta(r)$, where $\theta(r)$ is the spatially-dependent pulse angle. Contour plots of the B_1 field show that the excited volume is poorly defined.³ However it can be considerably improved by combining several pulses together to form a composite 'depth' pulse.⁸ The profile of selected M_{xy} has been demonstrated to be $\sin^n \theta(r)$, instead of $\sin \theta(r)$, where the value of n will depend upon the number of pulses that compose the depth pulse and upon the extent of phase cycling employed within the pulse. Depth pulses are often based upon the spin echo ($\theta(r); 2\theta(r)(\pm x, \pm y)$), where the use of $\theta(r), 2\theta(r)$ emphasizes the spatial variability of the B_1 field, ',' denotes a small time delay, and $\pm x, \pm y$ refer to the quadrature phases of the rf pulses. Analysis of the depth pulse approach involving the inversion-recovery sequence ($2\theta(r); \theta(r)(x); [2\theta(r)(\pm x, \pm y)_m];$) has also been demonstrated allowing volume localized relaxation measurements to be carried out.⁹

Composite pulses, whose initial usage was to compensate for pulse imperfections,¹⁰ have also been applied to the problem of spatial localization and complement the depth pulse approach.^{11,12} These composite pulses excite M_{xy} and sub-

sequent 180° pulses ensure that only signals experiencing a very narrow range of B_1 amplitudes actually form a spin echo. Contour plots of the inversion efficiency of these composite pulses demonstrate the potential of the method.^{13,14}

The duration and extent of phase cycling for both depth and composite pulse approaches can become large as the degree of localization is improved. Comparisons of the two techniques showed that depth pulses had improved performance with respect to frequency offset although they did require more phase cycling.¹⁵⁻¹⁷

3.2 Fourier Methods

Analysis of the depth pulse described above demonstrated that the spatial profile of M_{xy} generated by the surface coil transmitter could depend on $\sin^n \theta(r)$, where n is an odd integer and $\theta(r)$ the spatially-dependent pulse angle. Pekar et al. showed that any required region at depth from the transmitter coil can be constructed from the differing spatial harmonics generated with differing pulse power in the transmitter.¹⁸ Each harmonic is suitably weighted before accumulating a final signal response prior to Fourier transformation to obtain the localized spectrum. This harmonically analyzed sensitivity profile (HASP) technique has also been called Fourier series analysis,¹⁹ or Fourier series windowing (FSW).^{20,21} Unless each transient is accorded equal weight there is a loss of sensitivity; this loss is particularly exaggerated when the localization is required in the minimum number of transients. If unequal numbers of transients are accumulated for each of the generated harmonics, then the correct spatial profile can be obtained with no loss in sensitivity, but at the expense of increased scan acquisition time. There is the possibility of saving time by recognizing that some harmonics will not contribute greatly to the required spatial profile and need not be acquired.

The rotating frame zeugmatographic method of Hoult has been extended to the acquisition of spatially localized, high-resolution spectra.^{22,23} Incrementing the rf power level through a transmitter system generating an rf gradient produces a series of spatially-encoded transients. Each transient has to be recorded and stored separately rather than weighted and coadded as in the Fourier series method described previously. The resultant two-dimensional data set can be Fourier transformed in two directions to generate planes of conventional spectra.²³⁻²⁵ In this simplified method there is a loss of sensitivity of $\sqrt{2}$ since the transients are amplitude modulated by the exciting pulses and the longitudinal component of magnetization M_z remains undetected. However this loss of sensitivity can be recovered by an orthogonal 90° B_1 pulse which precesses all magnetization into the transverse plane, converting amplitude spatial encoding to phase modulation.^{22,26} This additional pulse should not be dependent upon the B_1 field and will usually be either of a composite or adiabatic nature. It should also be noted that the same approach can be applied to the Fourier series window technique described in the preceding paragraph. Strictly, the B_1 gradient should be spatially linear and Helmholtz transmitter coils have been proposed for this purpose.²² It has been noted that the surface coil response [equation (1)] is approximately linear along its axis in the range $0.3R$ to $0.8R$ and that this linearity is insignificantly distorted for small off-axis distances ($<0.5R$).²⁵ More complex rf

systems are required to introduce a second spatial dimension by providing an additional orthogonal linear B_1 field gradient. Applications employing these Fourier rf techniques are described in *Rotating Frame Methods for Spectroscopic Localization*.

4 B_0 FIELD GRADIENT TECHNIQUES

The wider application of MRI hardware in the form of magnetic field (B_0) gradient coils has allowed the development of a number of methods that provide much of the required flexibility for the acquisition of in vivo MRS data. These techniques may involve oscillatory gradients, slice selective methods, or Fourier techniques.

4.1 Sensitive Point Method

The magnetic field can be dynamically profiled by the application of sinusoidally varying B_0 field gradients.²⁷ Non-time-dependent signals are derived only from the isocenter of a field gradient system and these can be extracted by low-pass filtering. The isocenter can be controlled by adjustment of the balance of the current between the two halves of the gradient coil set. Localization to a volume in space has been achieved by the use of three orthogonal gradients with differing time-dependences. Signal is usually sampled under the steady-state regime ($TR \leq T_2, T_1$) and then the rf pulse repetition rate must exceed the gradient frequency. If this is not achieved, then the gradient oscillations are superimposed upon the time domain signal and artifactual sidebands can occur in the resultant spectra. By sampling the echo rather than the FID of the steady-state signal, it has been demonstrated that these artifacts can be reduced.²⁸

4.2 Slice-Selective Techniques

The degree of spatial localization offered by slice-selective pulses has led to their widespread use for in vivo MRS. Control of voxel dimension by gradient strength and rf pulse bandwidth and voxel position with rf carrier offset provide flexible positioning of regions from which signals are derived.

Common problems concern the generation of eddy currents by the pulsed gradients employed with these techniques, chemical shift artifact, and loss of initial portions of the signal. The absence of eddy currents remains an underlying strength of the B_1 gradient methods described earlier. The problem has been alleviated by a number of compensation (see *Eddy Currents and Their Control*) and correction schemes (see *Quantitation in In Vivo MRS*) and by the development of self-shielded gradient systems (see *Gradient Coil Systems*).

Chemical shift dispersion amongst individual resonances of a spectrum leads to a misplacement in position when pulsed B_0 field gradients are employed in slice-selective procedures. The extent of this chemical shift artifact or mis-registration is given by $\delta/\gamma G$ mm, where δ is the dispersion expressed in hertz (Hz) and γG is the field gradient (Hz mm^{-1}). The positional difference becomes more pronounced as the chemical shift increases, at higher field strengths, or in ^{13}C rather than ^1H MRS, but can be alleviated by use of the largest gradient possible. The use of high gradient values places a requirement for wider bandwidth, higher

power rf pulses, and a greater penalty in terms of increased eddy currents. In reality, following these measures, the misplacement for in vivo ^1H MRS may be less than 1 mm. More detail is given in *Selective Excitation Methods: Artifacts*.

The loss of initial data points of the digitized signal can arise through the finite time required to switch the gradient from one value to the next. Each data point lost represents a 180° phase roll across the resultant spectrum, which in poorly-resolved in vivo MRS, has proved intractable in the most rigorous sense. A number of baseline correction schemes have been suggested or, as an alternative, fitting the time domain data directly rather than introducing the artifact with the use of the Fourier transform (see *Quantitation in In Vivo MRS*). The extent of signal loss can be reduced with greater gradient strength and switch rates, eddy current control, and sequence development. The latter provide the material for the discussion below.

Slice-selective pulses are employed in three distinct ways; the signal from the required volume may be prepared along the z axis or in the xy plane, or alternatively the magnetization from unwanted regions may be presaturated by a series of slice-selective pulses.

4.2.1 Longitudinal Spatial Preparation

A number of techniques have been described that prepare signal from the required region of interest parallel to the static field B_0 . During the volume-selective procedure, unwanted M_{xy} is dephased by field gradients or alternatively by a phase cycling scheme during the acquisition of the data. The required signal, which is maintained along the z axis, is observed with a single broadband pulse. Loss of signal and time delay to the start of data acquisition are kept to a minimum by this approach which can be extended to include spin echo techniques as required.

Image selected in vivo spectroscopy (ISIS) consists of three orthogonal slice-selective 180° pulses in combination with a phase cycling scheme.²⁹ The phase cycling and data accumulation required introduce a minimum of eight transients before the volume localized spectrum can be observed. This represents a serious inconvenience when shimming is undertaken prior to the accumulation of the data. The technique has been extended to include the multiple acquisition of several voxels simultaneously,³⁰ and conformation of the voxel shape to match required pathological regions.³¹ ISIS, these developments, and its applications to ^{31}P MRS are described in *Single Voxel Whole Body Phosphorus MRS*.

Volume selective excitation (VSE) is a single shot localization technique based upon a composite selective procedure (45° , 90° , 45°) where both the 45° pulses are slice selective and the 90° is broadband.³² The required 'in-slice' material is inverted longitudinally while the unwanted magnetization is left in the transverse plane. Care must be taken to avoid the generation of stimulated echoes. Three orthogonal composite slice-selection pulses are required to define a single voxel and these are performed sequentially. VSE requires high rf power if the gradient is *not* switched during the broadband 90° pulse. VSE has been applied to the acquisition of ^{13}C and ^{31}P spectra.^{33,34} A comparable technique (DIGGER)³⁵ has improved the off-resonance capability and does not rely upon phase cycling by paying attention to the qualities of the individual rf excitation pulses.

The solvent suppressed spatially resolved spectroscopy (SPARS) technique alleviates the high rf requirement of VSE by introducing gradient switching and the spin echo into the localization to reduce the effects of the duration of the procedure.³⁶ Each of the required spatially selective pulses is a 90° , 180° , 90° sandwich, where *only* the final 90° pulse is slice selective. Unwanted signal remains in the transverse plane to be dephased and its cancellation can be improved by phase cycling. A similar technique (SPACE)³⁷ has also been proposed that employs the same rf pulse composite as SPARS. However, in this case, the first 90° is spatially selective and subsequent pulses are phase cycled to improve the suppression of unwanted signals.

4.2.2 Transverse Spatial Preparation

These techniques prepare the required signal in the transverse plane which can make them particularly vulnerable to loss of signal through T_2^* decay unless spin echo methods are introduced. Significant initial data loss can also occur, with subsequent increase in baseline roll in the resultant spectra, without the use of the spin echo. Despite these shortcomings, these methods have been widely employed to acquire ^{31}P and ^1H spectra.

Depth resolved surface coil spectroscopy (DRESS) represents the simplest of localization techniques, a single slice selective 90° followed by the acquisition of the data.³⁸ The lateral extent of the selected plane is controlled by the use of the surface receive coil and the selected region is usually assumed to be a disk. A slice-interleaved version of DRESS (SLIT-DRESS)³⁹ allows more spectroscopic data to be acquired by using offset slices during the inevitable relaxation delays. DRESS methods and applications are described in *NMR Spectroscopy of the Human Heart*.

Spin echo techniques can be introduced to alleviate time delay problems. Point resolved surface spectroscopy (PRESS) employs three selective pulses (90° , 180° , 180°) to leave M_{xy} from the required voxel to contribute to the final echo.⁴⁰ PRESS is particularly amenable to the acquisition of ^1H spectra where the increased echo time can be integrated into the scan as an additional suppression of unwanted fat and lipid signals. In this case the localization is preceded by a chemical shift selective (CHESS) pulse in order to presaturate the large water resonance (see *Selective Excitation in MRI and MR Spectroscopy*). A related technique that is applicable to ^1H MRS, the multiple echo spectroscopic acquisition (MESA) method,⁴¹⁻⁴³ employs three mutually orthogonal slice selective pulses to define to a given region of interest. Initial transverse magnetization is generated by a binomial excitation where the large water resonance remains along the B_0 axis and undetected (see *Water Suppression in Proton MRS of Humans and Animals*). The MESA sequence (1331 , 180° , 180° , 180°), like many multiecho techniques, places emphasis upon the quality of the refocusing 180° rf pulses, and unwanted signals can be substantially reduced by phase cycling.

Stimulated echo pulse sequences have been proposed to perform spectroscopic localization.⁴⁴⁻⁴⁶ The stimulated echo acquisition mode (STEAM) sequence consists of three selective 90° pulses (90° , 90° , 90°), one in each of the three spatial orientations. During the period after the second 90° pulse, the TM period, the required signal is orientated along the z axis and so there is no loss in signal due to transverse relaxation. At all other points of the sequence, the required signal is in the

transverse plane and as such the STEAM sequence is included in this section. As with the multiecho PRESS sequence, ^1H spectra can be acquired by preceding the STEAM localization with a series of narrow band, CHESS water suppression pulses. Stimulated echoes are intrinsically half the intensity of their spin echo counterparts which would appear to be a considerable disadvantage. However voxel definition is superior, as a result of employing selective 90° rather than 180° pulses, and STEAM consistently provides shorter echo time sequences than its spin echo counterparts PRESS and MESA. In practice these features account for the widespread use of STEAM in the acquisition of ^1H spectra (see *Single Voxel Localized Proton NMR Spectroscopy of Human Brain In Vivo*).

4.2.3 Spatial Presaturation

Maintaining the coherence of the signal from the required voxel can be alleviated by the use of spatial presaturation. Slice-selective pulses are used preferentially to excite the unwanted regions into the transverse plane to be dephased prior to the use of a single broadband pulse to observe the required signal. Time delays to the start of data acquisition can be reduced to a minimum suitable for shorter T_2 species.⁴⁷ This approach has been integrated into other localization schemes and has been called outer volume suppression (OVS).^{48–50} This approach has been particularly useful in the acquisition of ^1H spectra where the spatial presaturation of high scalp fat and lipid signals is required.

4.3 Fourier Methods

In contrast to the B_1 Fourier methods described earlier, where amplitude spatial-encoding has to be converted to phase modulation in a two-step process,²² B_0 field gradients act directly upon the transverse components of magnetization and generate spatial phase modulation directly into the signal. In most other respects the B_0 methods introduced here mirror those B_1 techniques described earlier.

The harmonically analyzed approach to spectral localization has been described by the application of a field gradient pulse within a spin echo pulse sequence.⁵¹ A number of transients are recorded with differing combinations of gradients in the x , y , and z directions to achieve full volume localization. Each transient can be Fourier-transformed to give spatially phase distorted spectra. Suitable weighting of each of these spectra prior to accumulation gives the desired volumetric region. The weighting factors employed are simply the Fourier coefficients of the desired region of interest. Weighting is best achieved by accumulating different numbers of transients for the various gradient permutations in order to maintain sensitivity.⁵² It has also been noted that the required region may be repositioned with respect to the gradient isocenters by multiplying each time domain transient in the acquired matrix by a phase factor $\exp(-i\gamma G_r r_0 t)$, where r and r_0 may refer to either x , y , or z components of the voxel's position.

Rather than weight and accumulate signals to achieve the required level of localization, it is possible to submit the data to a multidimensional Fourier transform.^{53–56} The resultant chemical shift image is a matrix of voxels, each containing a high-resolution spectrum. Chemical shift imaging or phase-encoded spectroscopy has been widely applied to the acquisition of ^1H , ^{19}F , ^{31}P , and ^{13}C in vivo spectra and is described in detail in

Chemical Shift Imaging. In situations of low S/N, which is inevitable for human MRS at low field with a poor filling factor for the remote regions of interest, this Fourier approach represents the most efficient of data acquisition procedures. In addition, since spatial resolution is expected to be low because of low concentration, the gradient usage is considerably less than the slice-selective techniques described in preceding sections with commensurate decrease in eddy current problems.

Consideration of the sensitivity, spatial response shape, and spatial location with respect to both harmonically analyzed and full Fourier approaches is given by Mareci and Brooker.⁵⁷

4.4 Nonlinear Gradients

A method involving surface gradients has been described earlier which involves the use of nonlinear, pulsed B_0 field gradients.⁶ It has also been noted that slice-selective procedures in nonlinear gradients can generate multidimensional spatial localization.⁵⁸ However the development of two- and three-dimensional spatially-selective pulses and spectro-spatial-selective pulses, both with the convenience of linear gradients, may overshadow this work (see *Complex Radiofrequency Pulses*).

5 PRACTICAL APPROACHES AND HYBRID TECHNIQUES

It is very difficult to make statements concerning the best technique for spatially-resolved in vivo MRS given the wide range of methods available. It is not surprising, given this comment, that the practical approach to spectral localization is to employ some hybrid of the techniques described beforehand. In a number of cases this hybrid approach may naturally occur through the availability of the relevant components of hardware.

The lateral spatial extent of signal, when employing a surface coil, may be controlled with any of the slice-selective techniques described earlier. This may require the use of adiabatic, hyperbolic secant⁵⁹ or frequency modulated rf pulses to compensate for the inhomogeneous B_1 field if a surface transmitter coil is employed. ISIS has been employed in this manner, in combination with depth pulses, to acquire ^1H spectra.⁶⁰ A similar approach, employing a two-dimensional ISIS method in sequence with DRESS,^{40,61,62} has been used to acquire examples of good quality ^{31}P muscle spectra. Two-dimensional ISIS, which defines a column of tissue after a four transient addition/subtraction cycle, has been employed with the B_1 Fourier series window technique.⁶³ In this case nine Fourier harmonics were acquired over 96 transients to obtain canine myocardia spectra in conjunction with a 29-mm surface transmit/receive coil. Phase modulation was implemented to improve sensitivity with this ISIS/FSW approach,^{26,64} where additional flexibility was provided by voxel shifting the acquired data matrix to overlay the required region of interest.

Proton MRS in many ways presents the largest technical problems in spectral localization due to the intense resonances of water and lipid. This is compounded by the narrow range of ^1H chemical shift dispersion available at the relatively low fields offered by whole body in vivo MR systems. Robust practical approaches involve spatial presaturation (OVS), in addition to

the volume selected procedure offered by STEAM, PRESS, and MESA,⁴⁸⁻⁵⁰ in order to control the large signals from peripheral fat layers. Water suppression may be either by narrow-band CHESS or binomial pulses. Fourier encoding has also been employed to localize further the ^1H signals within the defined region of interest. In a number of examinations the extent of this localization may not be fully required or warranted, but will provide a level of robustness across a number of eventualities.

The slice-selection techniques are usually introduced as single voxel methods that generate a single high-resolution spectrum from a predetermined position located by MRI. These offer the possibility of obtaining good quality spectra from regions where B_0 homogeneity may not be at its best. Local shimming of these selected volumes can compensate, to an extent, for the local difficulties caused by tissue interfaces or hemorrhagic pathology for example.^{65,66} The Fourier, or multi-voxel, methods require a much larger volume of high-quality field since data are acquired from all voxels simultaneously with the possibility of studying a wider field of view. When S/N is low and extensive data accumulation is necessary, and local deviations in field homogeneity are small, it makes sense to employ Fourier techniques by running the required spatial encoding in parallel with the required averaging. Since signal and noise are derived with equal weight and from exactly the same tissue volume, these methods make for efficient data acquisition. However the limited number of spatial harmonics that may be acquired, particularly when localization is extended into three dimensions, means that the degree of localization is intrinsically poor. Large changes in spectral appearance, when they occur very locally, are not well perceived due to voxel bleeding.⁶⁷

A number of comparisons have been made in relation to the variety of slice-selection methods. The use of selective 90° pulses for STEAM localization has been demonstrated to give better voxel definition than the inversion pulses of PRESS.⁶⁸ ISIS, PRESS, and STEAM have also been compared with respect to selection efficiency, selection contamination, and water suppression.⁶⁹ The minimum echo time TE for ISIS is much less than either STEAM or PRESS, and this tends to dominate such comparisons. The addition/subtraction requirement of ISIS was identified as a source of baseline distortion that is not readily apparent in the single-shot PRESS and STEAM techniques. Further comparisons between STEAM and PRESS have been made with respect to spin displacement (flow and diffusion effects),⁶⁸ minimum TE ,⁶⁸ effect of TE upon ^1H spectra quality and appearance,⁷⁰ water suppression,⁶⁸ effects of rf pulse miscalibration,⁶⁸ and homonuclear coupling effects.^{68,71,72}

An important point concerning rf power deposition is highlighted in a comparison between SPARS and STEAM,⁷³ where the broadband pulses of the SPARS method put it at a serious disadvantage. It was also noted in this work that the intrinsic insensitivity of the stimulated echo is not usually an overbearing issue since SPARS includes periods of irreversible dephasing during its localization period.

All the techniques presented previously have the attribute of acquiring conventional MR absorption spectra. Chemically shift selective pulses can be employed to excite a single resonance within a spectrum. Conventional and fast MRI techniques can then be employed to perform the degree of spatial localization required with greater efficiency.

6 BEYOND LOCALIZATION

A number of techniques discussed earlier, and in particular those applied to the acquisition of ^1H spectra, have moved beyond simple localization requirements and include additional methods for reducing the magnitude of strong, unwanted signals. In addition, a number of techniques have been investigated for the incidental or artifactual effects of flow and perfusion,⁶⁸ and homonuclear coupling phenomena.^{71,72} It is likely that in vivo MRS will parallel earlier developments in high-resolution NMR by employing such dependences to improve spectral sensitivity. There have been reports of both diffusion-weighted MRS,^{74,75} and editing,⁷⁶ polarization transfer,⁷⁷ and double quantum filtering.^{78,79}

McKinnon and Boesinger⁷⁶ have defined the three consecutive slice-selective pulses, as employed in the MESA technique, as a volume selective refocusing (VSR) sequence that may be subsequently integrated into a wide range of existing spectral editing techniques. More recent developments in spectro-spatial pulses give potential to allow the spatial localization and editing processes to occur simultaneously (see also *Complex Radiofrequency Pulses*) and this will further extend the quality of spectral information derived from the relatively low fields currently offered by whole body MR scanners.

1 INTRODUCTION

In vivo NMR spectroscopy offers a noninvasive window on metabolism and physiology in healthy and diseased humans and animals. Most initial efforts in NMR spectroscopy of living systems were devoted to the phosphorus and carbon nuclei. Because proton NMR is more sensitive, and allows access to a range of different metabolites, attention to proton spectroscopy has been increasing. However, without specific efforts to suppress water and fat resonances, the latter compounds completely dominate the in vivo proton NMR spectrum. For example, the effective concentration of water hydrogen atoms may be as high as 110M, whereas we wish to study metabolites in the millimolar range. Pioneering work on in vivo proton spectroscopy was performed at the laboratory of Shulman.^{1,2} Recent advances are now permitting in vivo proton spectroscopy and spectroscopic imaging of the human brain in a routine examination. The topic of this review is to outline the possible strategies to suppress the water resonance, and other unwanted resonances such as those of fat (triglycerides).

The suppression of solvent resonances is an area of research that has long been in the domain of high-resolution (HR) NMR. Many techniques were well established before in vivo proton NMR was even contemplated. Recent developments such as shielded field gradient technology, and shaped rf excitation pulses have played an important role in NMR imaging. Now, these advanced tools are among the most powerful assets for water-suppressed proton spectroscopy in vivo, as well as in vitro.

When compared with HR NMR, in vivo spectroscopy has to overcome several typical problems related to B_0 and B_1 inhomogeneity, and motion, regardless of the nucleus being studied. These problems increase dramatically in proton spectroscopy because of the additional problem of water suppression and the narrow proton chemical shift range. For example, the range of water resonance frequencies over the human head amounts to several ppm (especially outside the brain area), comparable to the chemical shift range of most observable compounds. Therefore, chemical-shift-based water suppression cannot work unless a very high degree of localization is achieved. The use of surface coil receivers may help to

avoid water signals from outside areas with a different resonance frequency. However, with the increasing attention being paid to spectroscopic imaging of large brain areas simultaneously, this solution is only of limited use. Motion effects further aggravate these problems.

Owing to limitations of space, in this article we emphasize general principles only, and highlight some important new developments. Because of the technical nature of this review, we do not restrict ourselves to human spectroscopy but also include important results in proton spectroscopy on animals. Detailed general reviews of water suppression in HR NMR and in vivo NMR have been published before.³⁻⁶

2 OVERVIEW OF SUPPRESSION METHODS BASED ON NMR AND OTHER BIOPHYSICAL PROPERTIES

2.1 Chemical Shift

Most suppression techniques are based on the frequency of the solvent resonance. Within this class of suppression strategies, we discriminate between methods that

1. accomplish a selective saturation of a frequency band before excitation of the spins of interest is started;⁷⁻¹⁹ or
2. avoid altogether the excitation of a frequency band;^{3,5,20,21} or
3. filter out a frequency band after signal reception.

In general, these methods have the disadvantage that all resonances of interest within the suppressed frequency band are also eliminated.

2.1.1 Selective Saturation

The general pulse sequence is

$$P_1 - d_1 (G_1) - P_2 \text{ Acq} \quad (1)$$

where P_1 is the soft rf pulse, d_1 is a short delay, preferably containing a gradient spoiling pulse G_1 , and P_2 is the excitation pulse followed by acquisition time or the rest of a more complicated pulse sequence. This sequence, with a constant amplitude P_1 and a duration of the order of the solvent T_1 (the 'presaturation' method⁷) is one of the most common water suppression methods in HR NMR. It is now well established that it is more effective to employ a selective (shaped) P_1 pulse using a flip angle slightly larger than 90° to take T_1 relaxation during d_1 into account, thus nulling solvent magnetization at the time of rf pulse P_2 .⁸⁻¹⁴ The latter technique, including a spoiling gradient,^{8,9} is often referred to as a CHESS sequence (chemical shift suppression). The method does not truly reflect a classical 'saturation' experiment. However, it leads to the condition of zero M_z magnetization and dephased transverse magnetization. In addition, selective magnetization inversion can be used followed by a waiting period to allow for zero M_z magnetization.¹⁵

The saturation procedure does not have to take place prior to the rest of the sequence. For example, a CHESS sequence can also be employed in the middle (TM) period of the stimulated echo sequence in in vivo NMR, when the magnetization due the resonances of interest is longitudinal. The basic

sequence can be repeated for increased efficiency. However, care should be taken that different gradient directions and powers are used to avoid unwanted echoes of the solvent resonance. A detailed analysis has been presented previously.¹² Examples are given in Figure 1.

A B_1 gradient may also be helpful in suppressing a frequency band.^{16–19} A combination of hard pulses followed by spin locking procedures has been proposed for in vivo NMR.^{18,19} The basic idea is that all off-resonance magnetization will dephase in the inhomogeneous spin locking field. In addition, a fast pulse train of hard pulses (DANTE²⁰) given with an inhomogeneous B_1 field has also been shown to lead to rapid effective nulling of longitudinal magnetization of solvent.^{16,17} These techniques are particularly useful for surface coils.

2.1.2 Excitation Profiles with a Gap at the Water Frequency

The difference in evolution frequency of transverse magnetization between solvent and solute can be employed to create a gap in the effective excitation profile at the solvent frequency.^{3,5,21} The best-known and widely used is the so-called jump–return sequence of Plateau and Guéron.²¹ The sequence starts with a $\frac{1}{2}\pi$ rf pulse with the transmitter on the solvent resonance. Following an evolution period t , a second $\frac{1}{2}\pi$ rf pulse is given with opposite phase. The magnetization of the solvent resonance is thus put back along the z axis. However, for a resonance with a relative frequency of $(4t)^{-1}$ with respect to the offset, the transverse magnetization will have rotated during t exactly 90° , and thus will remain unchanged by the second rf pulse. The frequency profile of such a sequence is approximately a sine function. Instead of two rf pulses, an increasing number of rf pulses can be used to improve the frequency profile. A disadvantage is the sometimes complicated phase roll over the spectrum. Shaped, self-refocusing rf pulses can improve the phase response dramatically.²² Guéron et al.⁵ have given a detailed review of this class of suppression techniques, along with further improvements.

Continuous wave (CW) and rapid scan techniques are based on a rapid sweep of the frequency band of interest and avoidance of the solvent resonances. However, these methods are now rarely used because of their low S/N per unit time.

2.1.3 Suppression of Water Resonance Following the Complete Pulse Sequence

When radiation damping is not a problem, the solvent resonance can be suppressed following the complete pulse sequence. The disadvantage is that even a very large dynamic range analog-to-digital converter ADC can often not handle the large voltage differences due to resonances of interest and solvent^{3,6} (Section 3.3).

2.2 Relaxation

Differences in relaxation times T_1 and T_2 between solutes and solvent can be exploited to achieve a relative suppression of the water resonance. T_1 and T_2 values of some brain compounds have been given by Frahm et al.²³ If the solvent suppression mechanism is entirely based on relaxation differences, signal loss for the resonances of interest can be significant, because differences in relaxation times are not dramatic. The advantage

Figure 1 Examples of high quality water suppression in in vivo proton spectroscopy of (a) human and (b) animal brain. (a) In vivo proton NMR spectrum of an 18 ml volume obtained from normal gray matter of a healthy volunteer. The spectrum is obtained with STEAM localization ($TR/TE/TM = 6000/20/30$ ms), and three preceding CHES water suppression procedures. The spectrum was obtained in approx. 6 min. A 2.0 T instrument was used, with a conventional quadrature head coil. Only exponential multiplication was used prior to FT, and no further data manipulation was applied. Courtesy of Dr. Jens Frahm, Biomedizinische NMR Forschungs GmbH, Max Planck Institut für Biophysikalische Chemie, Göttingen, Germany. (b) In vivo proton NMR spectrum from a 0.7 mL volume located in the superior part of the cat brain using STEAM localization ($TR/TE/TM = 1000/18/80$ ms). A 4.7 T instrument was used, equipped with 20 mT m^{-1} shielded gradients. A surface coil (outer diameter 48 mm) was used for transmission and reception. Three preceding CHES water suppression sequences, and three CHES water suppression sequences in the TM period were used. Lorentzian-to-Gaussian transformation was used prior to FT. For more details, see Moonen and van Zijl.¹²

of relaxation-based water suppression is that its mechanism is not frequency-selective, and therefore the method works regardless of the actual resonance frequency of water.

2.2.1 T_1 -Based Methods

The general pulse sequence is as above. When P_1 in sequence 1 is a π pulse, and d_1 is a delay adjusted for zero longitudinal magnetization of water,^{15,24,25} the sequence is often called a WEFT (water-eliminated Fourier transform). To avoid T_1 weighting of the resonances of interest, a selective π pulse can be used (see also Section 2.1.2). T_1 -based methods require more time than CHESS-type methods to null M_z solvent magnetization (because of T_1), and are optimal only for a single T_1 . In the case of more than two solvent populations with different T_1 s, more inversion pulses can be used, with adjustable delays between π pulses.²⁵

2.2.2 T_2 -Based Methods

A general spin echo (or stimulated echo) sequence can be used, such as

$$P_1 - \tau - P_2 - \tau \quad \text{Acq} \quad (2)$$

where P_1 is the $\frac{1}{2}\pi$ excitation pulse, 2τ is the echo time, and P_2 is the refocusing (π) pulse. Acquisition is started at the top of the echo, or immediately following the P_2 pulse. Apart from water suppression, the spin echo sequence has the added advantage of the removal of broad resonances (owing to short T_2). The reduced overlap is often helpful for quantifying resonance intensities, for example in proton spectroscopic imaging. A disadvantage is the phase modulation due to J coupling. However, when several refocusing pulses are used, specific J modulation patterns of molecules of interest can be turned into an advantage, for example for selecting lactate and avoiding uncoupled resonances.²⁶

2.3 Scalar Coupling

Many modern methods use nuclear coupling characteristics to select only coupled resonances and thus suppress the (single) solvent resonance automatically.^{27–49} These methods are identical to many of the so-called ‘editing’ techniques. Some techniques can be understood in sufficient detail using a classical vector presentation, whereas some newer methods can best be treated with the modern coherence pathway formalism. We shall first explain some basic methods for heteronuclear applications (e.g. proton detection of ^{13}C -labeled compounds). For the sake of simplicity, we shall limit the discussion to weakly coupled AX systems.

2.3.1 Indirect Detection by Spin Echo Methods

The heteronuclear spin echo difference method (POCE, proton-detected carbon editing) is a two-scan experiment in which the heteronuclear π pulse is turned on/off in alternating experiments.^{43,44,46,47}

$$\begin{aligned} {}^1\text{H} : & \frac{1}{2}\pi - \tau - \pi - \tau \quad \text{Acq} \\ {}^{13}\text{C} : & \quad \pi \quad (\text{on/off}) \end{aligned} \quad (3)$$

The optimum delay τ is $(2J)^{-1}$. The evolution of the multiplet can be easily followed in the rotating frame. If the heteronuclear π pulse is off, the coupled spins change the direction of their evolution at the time of the π pulse. As a result, the components of the multiplet rephase at the top of the echo. If both π pulses are on, the chemical shift is rephased at the top of the echo, but evolution due to the coupling has continued for a period J^{-1} . As a consequence, the multiplet has opposite phase. Subtraction thus gives resonances only for coupled spins and eliminates those for all noncoupled spins.

2.3.2 Indirect Detection by Polarization Transfer and Multiple Quantum Methods.

So far, we have discussed spin systems in terms of longitudinal and transverse magnetization. A more general treatment involves the analysis of coherence orders during the pulse sequence, and is particularly useful for the understanding of polarization transfer and multiple quantum pulse sequences. Coherence orders are denoted by p , where $p = 0, \pm 1, \pm 2$ for zero, single, and double quantum order, respectively. For an introduction to the coherence formalism, the reader is referred to the literature.^{27–29} We shall review two fundamental heteronuclear (^1H - ^{13}C) sequences here. Proton spins will be indicated by I , carbon spins by S . The single quantum coherences, $\hat{I}_x$ and $\hat{I}_y$, refer to the classical transverse (observable) proton magnetization, $\hat{S}_x$ and $\hat{S}_y$, to single quantum carbon magnetization. $2\hat{I}_x\hat{S}_y$ consists of double quantum coherence and zero quantum coherence, and is not directly observable. $2\hat{I}_x\hat{S}_z$ and $2\hat{I}_z\hat{S}_x$ are so-called antiphase single quantum coherences. Radiofrequency pulses may generate transitions between coherence orders, but gradient pulses cannot. The complete pulse sequence can be seen as a coherence pathway vector $\mathbf{p}$ with as many elements as rf pulses in which the coherence order in period i is indicated with order p_i .

As an example, we shall follow an HMQC (heteronuclear multiple quantum coherence)^{38,39,48,49} experiment (for the pulse sequence see Figure 2a). Following excitation of the protons ($\hat{I}_z \rightarrow -\hat{I}_y$) by the $\frac{1}{2}\pi$ rf pulse along the x axis in the rotating frame and neglecting the chemical shift, evolution of $\hat{I}_y$ will then lead to

$$-\hat{I}_y \xrightarrow{\text{evolution}} -\hat{I}_y \cos(\pi J_{IS}t) + 2\hat{I}_x\hat{S}_z \sin(\pi J_{IS}t) \quad (4)$$

The carbon pulse after an evolution period of $(2J)^{-1}$ will transfer the antiphase single quantum coherence into a multiple quantum coherence:

$$2\hat{I}_x\hat{S}_z \xrightarrow{\frac{1}{2}\pi_x^S} -2\hat{I}_x\hat{S}_y \quad (5)$$

The π proton pulse converts the zero-quantum into a double-quantum coherence, and the double-quantum into a zero-quantum coherence. The final $\pi/2$ carbon pulse transfers the $2\hat{I}_x\hat{S}_y$ coherences into observable antiphase proton magnetization ($2\hat{I}_x\hat{S}_z$ coherence), which is first allowed to refocus and then detected.

Figure 2(b) shows an HSQC heteronuclear polarization transfer experiment (heteronuclear single quantum coher-

Figure 2 Coherence pathways and pulse sequences for (a) heteronuclear multiple quantum coherence (HMQC) and (b) heteronuclear single quantum coherence (HSQC) experiments. The phase of the rf pulses is irrelevant for the sequence when gradients G_{sel} and G_{add} are used for coherence selection. The phase of the rf pulses, and the multiscan phase cycle, is important when no gradients are used. Reproduced, with permission, from Ruiz-Cabello et al.⁴⁸ (c) ^{13}C - ^1H HMQC spectra obtained from cat brain in vivo (upper spectrum), and 45 min following sacrifice (lower spectrum). Both spectra were obtained in 3 min 19 s from an 8 mm slice through the cat brain following infusion of ^{13}C -labeled glucose (final blood glucose level was 16.6 mM). Spectra are not ^{13}C -decoupled, and show ^{13}C multiplets. Note the complete absence of the water resonance. Assignments are: (1) α -[^{13}C]glucose; (2) β -[^{13}C]glucose; (3) [2- ^{13}C]glutamate and glutamine; (4) [4- ^{13}C]glutamate and glutamine; (5) [3- ^{13}C]glutamate and glutamine; (6) [3- ^{13}C]lactate. (d) Two-dimensional ^{13}C - ^1H HMQC correlation spectrum obtained in a fully decoupled mode by incrementing the multiple quantum period. Total acquisition time was 30 min. The projections along the ^1H and ^{13}C axes are shown as well. Assignments are as in (c). Note the separation in peak 4 corresponding to a separation of the glutamate (peak a) and glutamine (peak b).

ence⁵⁰). Following evolution as in the HMQC experiment [equation (4)] and refocusing of the chemical shift, the essential step is the simultaneous proton and carbon $\frac{1}{2}\pi$ pulses, which create antiphase carbon magnetization from antiphase proton magnetization ($2\hat{I}_x\hat{S}_z \rightarrow 2\hat{I}_x\hat{S}_y$). This is an effective polarization transfer from the proton spins to the coupled carbon spins. Now, the carbon nuclei can be detected with an enhanced polarization (the enhancement is γ_H/γ_C). The basic experiment is called the INEPT experiment. For maximum enhancement, a second (inverse) polarization transfer is carried out, and the sensitive hydrogen nucleus can be detected for optimum efficiency. Note the coherence pathway diagram in Figure 2(b).

When selecting a unique coherence pathway of Figure 2, noncoupled resonances are automatically eliminated. Therefore, coupled resonances under the water line can, in principle, be measured. However, note that the coherence pathway selection is generally a multiscan experiment (see Section 3.1 for important exceptions). The reason is that the rf pulses also lead to undesired coherences. This may be caused by the inhomogeneous B_1 field, or by unwanted coherences that are generated even when ideal $\frac{1}{2}\pi$ pulses can be used (for example, owing to relaxation effects). In order to avoid the detection of unwanted coherences, the phase of the rf pulses and the receiver are varied using a phase cycling scheme.^{27–29} For the purpose of water suppression, it is important to note that in a multiscan experiment, the ADC resolution may still be a limiting factor.

Limitations of space preclude a thorough analysis here of all hetero- and homonuclear editing pulse sequences with automatic water suppression. Generally, similar principles hold for homo- and heteronuclear coherence pathways.^{27,28} However, note that single quantum evolution frequencies are similar in homonuclear sequences, whereas they are dependent on the gyromagnetic ratio of nucleus I or S in the heteronuclear case. Thus, a homonuclear editing sequence should involve either at least one rf pulse that avoids water excitation, or a multiple quantum order in part of the sequence in order to inherently eliminate the singlet solvent resonance.

In short, multipulse editing sequences, based on polarization transfer and multiple quantum coherences, can be used for ‘automatic’ water suppression. Multiscan phase cycling schemes are necessary for pure coherence pathway selection. In Section 3.1.3, an important exception to this rule will be reviewed, namely, the use of field gradients for single scan coherence pathway selection.

2.4 Diffusion

The diffusion constant of water is considerably higher than that of small metabolites and much higher than that of macromolecules. Pulse sequences can be sensitized to diffusion by the use of B_0 magnetic field gradients without any effect on stationary molecules.^{51–54} For two gradient pulses of strength G and duration δ , and with duration Δ between their starts, the attenuated signal S resulting from free diffusion can be expressed as

$$S/S_0 = \exp[-\gamma^2 G^2 \delta^2 (\Delta - \frac{1}{3}\delta) D] \quad (6)$$

where S_0 is the starting signal and D is the diffusion coefficient. For long diffusion times, restrictions by cell membranes and binding to macromolecules have to be taken into account.

An additional advantage for water suppression is that the permeability of cell membranes to water is generally much higher than to most other compounds. The main disadvantage is that diffusion-sensitized pulse sequences are also very sensitive to motion. Therefore, such methods appear to have more potential for HR NMR than for in vivo NMR.^{52,54}

2.5 Exchange

Exchange of protons between a dissolved compound and solvent water can result in different relaxation properties of the water protons. These exchange properties can be used to attenuate the solvent resonance.⁵⁵ For example, the saturation of exchangeable spins, whether by rf irradiation, T_2 relaxation, or dephasing in a magnetic field, can be transferred to the water resonance. This exchange mechanism is the basis of the so-called ‘magnetization transfer contrast’ in MRI,⁵⁶ but has not been used for the specific purpose of solvent suppression in in vivo NMR.

3 ADVANCED HARDWARE AND SOFTWARE TOOLS

3.1 Pulsed Field Gradients

The development of high-quality pulsed field gradients is probably the single most important tool that has made the routine applications of proton spectroscopy possible in humans. Historically, pulsed field gradients were used in HR NMR to dephase (spoil) the transverse magnetization—hence the often used name of a homospoil pulse.⁵⁷ Although the fundamental advantages of field gradients were known,^{57–60} the limited quality with respect to amplitude, ramp times, current stability, and particularly residual gradients and vibration effects, prevented their general use. The extreme demands in MRI—in particular, with respect to the very fast echo planar imaging method⁶¹—have dramatically accelerated hardware developments. The advent of self-shielded gradient coils with minimal residual gradients should thus be viewed as a milestone.^{62,63} An outer gradient coil is used that cancels the outside field of the inner coil, thus eliminating eddy currents in the cryostat. Pulsed field gradient technology is now also becoming a routine tool in HR NMR. Field gradients are used for the following purposes:

1. rapid dephasing of transverse magnetization (homospoil pulse);
2. spatial encoding and spatially selective excitation (in conjunction with shaped rf pulses);
3. single shot coherence pathway selection;
4. creating diffusion sensitivity (Section 2.1.4).

3.1.1 Rapid Dephasing of Transverse Magnetization

Following a gradient pulse of duration δ with magnitude G_α in direction α , the phase ϕ_α at location r_α as a function of coherence order p is

$$\phi_\alpha(p) = p\gamma r_\alpha \delta G_\alpha \quad (7)$$

Therefore, a phase dispersion results that attenuates the transverse magnetization by a factor f :

$$\frac{1}{f} = \left| \frac{1}{r_2 - r_1} \int_{r_1}^{r_2} e^{-i\varphi_\alpha} dr_\alpha \right| \quad (8)$$

The limits r_2 and r_1 are the voxel dimensions in the gradient direction α . Equation (8) assumes equal spin density, and a homogeneous field. Note that the attenuation works as a result of the integration of the phase over the dimension of the volume.¹² In the case of spectroscopic imaging, the integration is over the voxel dimensions, not over the full object. The attenuation is higher with a higher gyromagnetic ratio, and with a higher coherence order. Homonuclear zero quantum order will thus not be dephased by the gradient pulse. Note also that the efficiency of the gradient crusher depends on the local static field homogeneity. For a detailed account, see Moonen et al.⁶⁴ Shimming is therefore important in the full region where high efficiency of gradient crushers is necessary, not only in the region of interest.

3.1.2 Spatial Encoding and Spatially Selective Excitation

The essence of field gradients in imaging is the encoding of spatial information,⁶⁵ whether used for phase encoding, frequency encoding, or spatially selective excitation. In proton spectroscopy of humans, field gradients are often employed for the same purpose.^{66–82} For spectroscopic imaging,^{83–89} phase encoding is generally used for spatial encoding in two or three directions. In conjunction with shaped rf pulses (leading to a desired frequency profile), field gradient pulses lead to spatially selective excitation or refocusing (see Section 4.2 for a more detailed account). The importance of spatial selection for water suppression purposes is further explained in Section 4.1. Spatial and spectral selection can be combined in a single rf pulse together with a special gradient waveform.^{89–91}

3.1.3 Single Shot Coherence Pathway Selection

Conventionally (Section 2.3), a coherence pathway is selected using a multiscan approach using specific phase cycles of rf pulses and receiver. However, this ideal result is often not reached in vivo as a result of motion or of instrumental instabilities. The selection can also be achieved using pulsed field gradients, often completely eliminating the need for phase cycling. For example, a π refocusing pulse at the end of a pulse sequence may generate transverse magnetization as a result of an inhomogeneous B_1 field. Using two scans with opposite phase of the π pulse, transverse magnetization is canceled. A pair of identical gradient pulses around the π pulse will lead to cancelation of the unwanted transverse magnetization in a single scan.

We can generalize equation (7) with respect to the phase of transverse magnetization at location r as a function of coherence order p during all periods i of the pulse sequence:

$$\phi_i(r) = \left(\sum_j p_j \gamma_j \right) r G_i t_i \quad (9)$$

where p_j is the coherence order of the individual nuclei (e.g. ^{13}C , ^1H) in period i and all other symbols have the same meaning as in equation (7). Thus, the phase evolves as a function of coherence order and gyromagnetic ratio, and equation (9) can be used to keep track of the phase evolution during the entire

pulse sequence. A certain coherence order can thus be selectively rephased if the following condition is satisfied:

$$\sum_i \phi_i(r) = 0 \quad (10)$$

In the ideal case, spins of interest are refocused after the last rf pulse, and a gradient scheme is employed that avoids any rephasing of undesired coherences.^{61,62} The required gradient power depends on the signal strength of the desired versus undesired coherences.

Localization, achieved by one or more spatially selective rf pulses, can be conveniently treated as a type of coherence pathway selection.^{12,64} When more rf pulses are employed during a pulse sequence, it becomes harder to ensure sufficient dephasing of all undesired coherences. However, the use of gradients in all three principal axes with different amplitudes, and using different combinations at different time points in the sequence, offers great flexibility to optimize the single scan coherence selection.

Using equation (9), it can be easily seen that a coherence pathway selection involving a double quantum evolution ($p = \pm 2$) leads to dephasing of the solvent resonance without recourse to any frequency-dependent water suppression. The example shown in Figure 3 demonstrates that resonances under the water line may be observed, such as the resonances of the biologically important glucose molecule. Heteronuclear polarization transfer can also be achieved in a single scan with complete water suppression. However, homonuclear polarization transfer or any homonuclear sequence with $p = 0, \pm 1$, without chemical-shift-selective pulses, cannot achieve this, and additional water suppression methods must be employed. However, even in such cases, the use of field gradient pulses is beneficial because of the elimination of phase cycling (less motion sensitivity), and, in conjunction with other solvent suppression techniques, decreased water signal per scan and thus fewer demands on the receiver system.^{94,95}

The use of field gradients for single shot coherence selection also has some disadvantages. Most important is the loss of a factor of two in the signal (except in the case of gradient pulses around a π refocusing pulse, and in special sequences using selective refocusing pulses³⁷ or sensitivity-enhanced gradient experiments⁹⁶). The reason is that only one coherence pathway is selected, whereas phase cycling allows pathways of opposite signs to be selected simultaneously. For correlated multidimensional NMR, a second disadvantage (and a consequence of the first) is that phase-sensitive 2D spectra cannot be obtained using a single scan per t_1 increment. When using a second scan with selection of coherence path with opposite sign of coherence order in the t_1 period, phased resonances can be obtained. Of course, if these disadvantages are serious, pulsed field gradients may still be used only around refocusing pulses, and thus still eliminate part of the phase cycle.

3.2 Shaped rf Pulses

Shaped rf pulses play an important role in MRI, especially in slice-selective excitation and refocusing.^{90–92,97–107} To a first approximation, the frequency response resulting from a particular rf pulse shape is given by the Fourier transform of the waveform. This is known as the linear response. For flip angles close to, and above 90° , linear response theory is no longer

completely accurate, and the Bloch equations have to be used to determine the response.^{5,108} Corrections to the basic sinc waveform are now commonly used in NMR imaging. In localized proton spectroscopy, shaped rf pulses are used for the same purposes. In addition, a frequency-selective excitation is often used to select a narrow frequency band at the water resonance. In contrast to slice-selective pulses, phase-coherent response is not desired for frequency-selective suppression. In other applications, it is useful to combine spatial and spectral selection in a single pulse. The different specifications in different pulse sequences clearly indicate the opportunities for a specific design of rf pulses. In modern applications, simple

Fourier transform of a desired frequency profile is often used as a starting point for a shaped rf pulse. Then, an optimization routine is used to arrive at improved shapes using the complete Bloch equations. Recent advances use complex polynomials for mapping the rf pulse and then solving them analytically.^{91,107}

The inhomogeneity in the B_1 field (e.g., of a surface coil) has advantages and disadvantages in this respect. One can use the B_1 gradient to advantage in order to arrive at a desired phase dispersal of the water magnetization following excitation (see Section 2.1.1). On the other hand, inhomogeneous B_1 fields lead to loss of signal due to a spread in flip angle and to a spatially dependent population of desired and undesired coherence pathways, often necessitating the use of large gradient crushers for coherence path selection. The latter disadvantage can be overcome by using adiabatic pulses.

3.2.1 Adiabatic rf Pulses

Most water suppression techniques demand precise flip angles. Despite high B_1 homogeneity in the modern volume coils that are now routinely available in whole body MR instruments, the range of the B_1 field may still exceed the requirements—in particular, for applications of water-suppressed proton spectroscopic imaging. Accurate flip angles, independent of the local B_1 field, can be achieved with adiabatic rf pulses.^{92,97–106} The first such pulses accomplished excitation and spin inversion, and employed a continuous frequency ramp of the B_1 field while maintaining a constant amplitude. The effect of this pulse can be visualized in the rotating frame by analyzing the direction of the effective field (a function of the B_1 field and the rf frequency relative to the Larmor frequency). During the pulse, the effective field B_e rotates from the positive z axis to the negative z axis (in the case of inversion) or to the (x,y) plane (in the case of excitation). So long as the B_1 field exceeds a threshold value (the adiabatic condition), the magnetization continues to rotate effectively with a small precession angle around the field B_e during the entire pulse. In other words, the magnetization M remains collinear with B_e above a threshold B_1 . Therefore, if we let B_e rotate by π then M will also rotate by π , and spin inversion is accomplished. The flip angle is independent of the B_1 field if the rate of change of the angle of the field B_e with

Figure 3 Unedited (a) and lactate-edited (b) localized proton spectra (volume $200\ \mu\text{l}$) of an intracerebral glioma in the rat obtained at 4.7 T with a surface coil for excitation in conjunction with adiabatic pulses ($TE/TR = 272/2000$ ms; 4 min acquisition time for each spectrum). The basic pulse sequence is a spin echo method with jump–return (Section 2.1.2) excitation and refocusing pulses for water suppression, combined [in (b)] with a frequency-selective inversion pulse at the resonance frequency of the C- α proton (4.1 ppm). The inversion pulse is alternated on/off, and the resulting signals are subtracted for the editing procedure.⁴⁷ All rf pulses have been replaced with adiabatic pulses. Instead of hard jump–return pulses, solvent-suppressive adiabatic pulses were used. The inversion pulse was an adiabatic DANTE pulse. To maintain better phase coherence in the editing procedure, a second (2π) adiabatic DANTE was inserted in the second $\frac{1}{2}TE$ period. Phase cycling using the EXORCYCLE procedure was performed. Localization was achieved with a modified 3D ISIS method using BIR-4 inversion pulses. Further details are given by Schapp et al.⁹² and de Graaf et al.⁹³ Courtesy of Michael Garwood, Center for Magnetic Resonance Research, University of Minnesota, Minneapolis, MN

the z axis remains much smaller than the rotation frequency of magnetization $\mathbf{M}$ around the effective field $\mathbf{B}_e$ (i.e., the adiabatic criterion). The frequency sweep does not need to be accomplished with a linear ramp. In fact, a whole range of frequency (or phase) modulation functions have been described. The effect of the different modulation functions affect the $\mathbf{B}_1$ and off-resonance range where the pulse remains adiabatic. The disadvantages of these original adiabatic pulses are that

1. they do not result in good slice profiles when used for slice selection;
2. they require increased rf power;
3. plane rotation is not possible.

The latter disadvantage, in particular, has prevented many applications, especially in areas related to coherence pathway selection and water suppression. However, recent advances have made it possible to perform adiabatic plane rotations and thus refocusing. In addition, slice-selective refocusing with adiabatic pulses has been made possible by using two consecutive adiabatic inversion pulses.¹⁰⁹

The problem of plane rotation using the above adiabatic pulses is that, unlike magnetization that is initially collinear with the effective field $\mathbf{B}_e$, magnetization perpendicular to $\mathbf{B}_e$ at location r will precess through an angle β depending on the actual magnitude of $\mathbf{B}_e$ at location r . This angle therefore varies with location, and, as a result, the possibility of $\mathbf{B}_1$ -independent rotation is apparently lost. The central idea behind the solution of Garwood, Ugurbil and colleagues^{92,102–104} is that if the effective field $\mathbf{B}_e$ is suddenly inverted, and if $\mathbf{B}_e$ is properly rotated, leading to a precession of $-\beta$ at location r , then the magnetization $\mathbf{M}$ will undergo an effective plane rotation. One of the most versatile of this new class of adiabatic plane rotation pulses is the so-called BIR-4 pulse.¹⁰⁵ The pulse consists of three sections: an adiabatic half-passage in reverse, adiabatic inversion, and adiabatic half-passage. Two inversions of $\mathbf{B}_e$ occur, for example, between periods one and two, and between two and three, accompanied by two discontinuous phase jumps, $\Delta\phi_1$ and $\Delta\phi_2$. The BIR-4 pulse can accomplish uniform plane rotations through any angle, the magnitude being determined by the phase jumps $\Delta\phi_1$ and $\Delta\phi_2$.

The feature of BIR-4 that is uniquely suitable for water suppression purposes or coherence pathway selection purposes is the fact that the phase jumps can be accomplished not only using the phase of the $\mathbf{B}_1$ field, but also by the Larmor precession frequency or by J coupling.^{104,106} The first possibility is achieved simply by inserting a delay at the time of the phase jumps, leading to frequency-selective adiabatic pulses. The second possibility leads to adiabatic editing based on spin–spin coupling and adiabatic polarization transfer.¹⁰⁶ These elegant features can be accomplished with a high insensitivity of more than 10-fold variations in the $\mathbf{B}_1$ field. Figure 3 shows an example.

3.3 Postacquisition Frequency Filters

Even when the pulse sequence has resulted in water suppression of such high quality that the preamplifier has not been overloaded and the dynamic range of the ADC is sufficient with respect to the S/N of the experiment, it may be advantageous further to reduce the water line using data processing algorithms. The reason lies in some remaining disadvantages of the (suppressed but still dominating) water resonance. First, the base of the water line extends far into other regions of the

spectrum. Second, insufficient apodization and truncation of the time domain can cause ‘ringing’ over a large portion of the spectrum. The latter problem is especially relevant if the acquisition time is short, such as in fast spectroscopic imaging using multiple spin echoes.

Several data processing methods can be used to extract the information from the raw time domain signals. Baseline corrections and convolution difference methods have been used extensively.^{3–6} Much progress has been made in fitting in the time and frequency domains.^{110–112} The latter methods are preferred whenever additional a priori information is available about the spectrum. A simple approach—the frequency filter—is demonstrated in Figure 4. The method is robust, fast, and automatic.^{113–115} First, with water on resonance, a moving average filter over n data points is applied to generate a time domain signal from the raw data, which thus contain only data around zero frequency. Generally, a Gaussian weighting function is used, together with some extrapolation to determine the first and last $\frac{1}{2}n$ points. Second, the filter output is subtracted from the raw data. It has been shown that hardware frequency filters can also be implemented before the preamplifier stage.¹¹⁶

4 EVALUATION OF EXPERIMENTAL PROBLEMS

4.1 Spatial Selection

Most human proton spectroscopy is performed with the standard quadrature resonator. Therefore, signal detection is about equally efficient over the whole head, including the neck region. Owing to susceptibility differences over the complete sensitive volume, and also in part to nonideal shimming or magnet imperfections, water in some regions will have similar resonance frequencies to the metabolites of interest in the region to be examined. Two important conclusions can be drawn. First, frequency-based water suppression may work in a well-shimmed area, but not in the complete sensitive coil volume. Second, frequency-based water suppression only makes sense in conjunction with high-quality localization.

Localization may be performed using a surface coil for reception and transmission purposes.¹¹⁷ The relatively small coil limits the sensitive area and thus the source of artifactual signals. In addition, $\mathbf{B}_1$ gradients generated by the surface coil can be used for additional localization.¹¹⁸ Far more common is the use of $\mathbf{B}_0$ gradients, which are, of course, routinely available on every clinical MRI instrument. One of the first methods used a field profiling method to spoil resonances originating outside the region of interest.¹¹⁹ However, most methods employ switched $\mathbf{B}_0$ gradients for localization—either for phase encoding or for slice selection purposes.^{66–82} Slice selection in one direction is achieved similarly to common methods in MRI. Volume selection is achieved using a combination of three frequency-selective rf pulses in the presence of three mutually orthogonal gradients. This can be done in a multiscan^{66–70,73–76} or single scan^{10,70,71,78–81} approach. Selection in two or three different directions can also be achieved simultaneously.^{90,120} Outer volume suppression may help the localization process. Because of the very high degree of localization, and the presence of motion, single shot methods are preferred. Note the important additional role of the $\mathbf{B}_0$ gradients in single shot localization (e.g., crushers used for coherence

pathway selection without rf phase cycling). Phase encoding employing B_0 gradients can be used for additional localization in spectroscopic imaging with Fourier transform⁸⁴ or alternative data processing methods using a priori information.^{121,122} The quality of localization using phase encoding can be analyzed with the point spread function.

4.2 B_0 Inhomogeneity

Perhaps the most significant problem in *in vivo* proton spectroscopy is the attainable homogeneity in the static magnetic field B_0 . Air-tissue and fat-tissue interfaces may lead to susceptibility gradients of the same magnitude as the generally used frequency range in *in vivo* proton spectroscopy. High-quality field homogeneity can be obtained in the brain, but is rather difficult in almost all other organs and tissues. This is the reason why proton spectroscopy is most commonly used in brain. Limited B_0 homogeneity is not only detrimental to spectral appearance, but has also other disadvantages. Among these are

1. limitations in frequency-based water suppression methods;
2. errors in localization based on slice selection principles;
3. limitation in the efficiency of B_0 gradients for coherence selection and for rapid dephasing;
4. echo shifting when the effect of an incompletely compensated B_0 gradient is countered by the field inhomogeneity.

There are no complete solutions to the problem of limited B_0 homogeneity. Partial remedies include optimal (possibly local) shimming, selecting small voxels, and using self-shielded gradients. Methods have been presented that result in sharp lines despite B_0 inhomogeneities.¹²³ However, this result comes at the price of a severe S/N penalty.

4.3 B_1 Inhomogeneity

The disadvantages of limited B_1 homogeneity have been discussed in Section 2.1. In the context of water (or fat) suppression using the popular CHESS methods, the flip angle must be defined precisely. Recent advances in adiabatic pulse design may provide elegant improvements.

4.4 Motion

Motion is a common problem in MRI. Despite the much larger voxels in proton spectroscopy, it can be an even bigger problem in the latter technique—in particular, because of the extreme demands on water suppression and localization. In this regard, we may distinguish not only macroscopic motion of uncooperative patients, but also motion of arterial and venous

Figure 4 The use of a simple postprocessing frequency filter to limit detrimental effects of the suppressed but still dominant water resonance on spectral quality. The example is taken from a voxel of a water-suppressed spectroscopic image (for pulse sequence details, see Moonen et al.).⁶⁴ The raw time domain signals, and magnitude mode presentation following FT are shown in (a) and (b), respectively. The effect of the time domain frequency filter is shown on the filtered time domain (c) and the corresponding frequency spectrum (d) in magnitude mode presentation. Courtesy of Geoffrey Sobering, *In Vivo* NMR Research Center, NCRR, NIH, Bethesda, MD

blood, of CSF, and of brain tissue. The preferred method to minimize the detrimental effects of motion is to perform water suppression and localization in a single scan.¹² Multiscan phase cycling methods lead to incomplete suppression of unwanted signals in the presence of motion. However, single scan methods employing B_0 gradients are not without problems. For example, motion during the scan may result in a phase shift of the echo. Tracking the phase using an additional echo¹²³ may help if the phase shift is identical for the complete voxel, but is of limited use if it is spatially dependent. In addition, if signal averaging is used, the motion sensitivity may be decreased when magnitude spectra are averaged, instead of pure phase spectra. In addition, shifts in the echo position may occur as a result of an imbalanced gradient in the presence of field inhomogeneities resulting from the motion.

4.5 Spectroscopic Imaging

The typical problems and solutions for solvent suppression in single voxels are similar to those in spectroscopic imaging methods. However, since modern spectroscopic imaging⁸⁶⁻⁹¹ is performed in a single session covering a large part of the brain, problems with B_0 and B_1 inhomogeneities are more severe. The problem of B_0 homogeneity leads to the need for a larger frequency band affected by the water suppression procedure. Postprocessing water suppression (Section 3.3) is commonly used to minimize the effects of spatially dependent water suppression. Adiabatic pulses—now already routinely used for spin inversion purposes in spectroscopic imaging—may bring further improvements. Motion during spectroscopic imaging may lead to severe artifacts.

4.6 Fat Suppression

This article has dealt with suppression of the water resonance. Resonances of fat, or indeed, the family of triglycerides, can also dominate an in vivo proton NMR spectrum. Triglycerides lead to many resonances covering a large part of the useful proton spectrum. Therefore, typical frequency-selective suppression is not satisfactory. Three features of fat resonances are used for suppression purposes.

1. T_1 values are short (about 280 ms at 1.5 T), and can be used conveniently when preceding a pulse sequence with an inversion-recovery sequence.
2. In healthy brain tissue, no significant contributions originate from brain triglycerides.² The fat resonances arise predominantly from the skull tissue and can thus be suppressed by (a) outer volume suppression⁶⁷ (e.g., by spatial excitation of the entire skull area followed by rapid dephasing); or (b) avoiding excitation of skull area using accurate localization procedures (see Section 4.1).
3. Coupling patterns in triglyceride resonances, as distinct from those in the lactate doublet, are often used to separate the two compounds. Since the spatial origin of fat resonances is in the skull, phase encoding is helpful in defining the spatial origin of the fat signals, and thus suppressing the fat resonances in brain spectra.¹²⁴

4.7 Safety Issues

The potential safety issues in water-suppressed proton spectroscopy are the same as for routine MRI. There are no specific safety issues with regard to water suppression, except in some cases heat deposition by rf irradiation when employing (semi)-continuous rf irradiation or B_1 gradients to achieve scrambling of the water magnetization. However, most methods described in this article use less rf power per unit time than routinely used in multiple spin echo MRI methods.

5 SUMMARY

Solvent suppression has been, and remains, a rich area of research. Many advanced methods, developed over at least 30 years of high-resolution NMR, have been adapted for use in in vivo proton NMR spectroscopy. Water-suppressed human proton spectroscopy has now become almost a routine tool for brain NMR examination at 1.5 T. Although numerous developments have contributed to this extraordinary achievement, two fundamental technologies have been crucial:

1. the development of high-quality, fast switching, B_0 gradient coils, in particular, the invention of the self-shielded gradient coil;
2. the achievement of excellent rf phase and amplitude stability and control.

The latter technology is especially relevant for adiabatic and other shaped pulses. Together with excellent progress in the field of single shot localization, these developments have made high-quality, water-suppressed proton spectroscopy of human and animal brain a reality. Solvent suppression in spectroscopic imaging is similar, but not identical, to the problem of single voxel solvent suppression. However, recent progress indicates that automated single slice and multislice spectroscopic imaging of the human brain will soon be available on standard 1.5 T instruments. The technological challenge that still remains largely unsolved is the routine use of proton spectroscopy of organs other than the brain.

Biographical Sketches

Chrit Moonen. *b* 1955. M.S., 1980, Ph.D., 1983, Agricultural University, Wageningen, The Netherlands. Introduced to protein NMR by Kurt Wüthrich, Zürich, 1979. Faculty member, Department of Biochemistry at Wageningen 1984–86; sabbatical with George Radda, Department of Biochemistry, Oxford; one year with Morton Bradbury at University of California at Davis, 1987. Head of the NIH In Vivo NMR Research Center 1987–1996. Director of Research at the Centre National de la Recherche Scientifique, University of Bordeaux 2 1997–present. Approximately 100 publications. Research interests: mapping of brain function, physiological MR, diffusion and perfusion imaging, interventional MRI, MRI guided focused ultrasound.

Peter C. M. van Zijl. *b* 1956. M.S., 1980, Ph.D., 1985, Free University, Amsterdam, The Netherlands. Postdoctoral fellow at Carnegie Mellon University, Department of Chemistry, 1985–87; visiting associate at National Institutes of Health, National Cancer Institute, 1987–90. Research assistant professor at Georgetown University, Department of Pharmacology, 1990–92; Professor at Johns Hopkins Medical School, Department of Radiology, 1992–present. Approx. 75 publications. Research interests: in vivo spectroscopy and imaging of brain function, including diffusion imaging and imaging of metabolite levels and active metabolism of magnetically labelled precursors. Mechanism of ischemia. Design of NMR technology for HR NMR.

Animal Methods in MRS

David G. Gadian

Royal College of Surgeons Unit of Biophysics, Institute of Child Health, London, UK

1 INTRODUCTION

Magnetic resonance spectroscopy studies of animal models have contributed in numerous ways to our understanding of the metabolic processes that take place in normal and diseased tissue. Applications to tumor metabolism are covered in accompanying articles (see *Spectroscopic Studies of Animal Tumor Models*), and are therefore not discussed here. Space limitations do not allow a comprehensive review; instead, we concentrate in this article on three major themes in this research area, namely (i) ^{31}P MRS and tissue energetics, (ii) ^1H MRS of brain metabolites, and (iii) ^{13}C studies of intermediary metabolism, and we conclude with some illustrative examples of the role of MRS in the investigation of stroke models.

2 PHOSPHORUS-31 MRS AND TISSUE ENERGETICS

Following earlier NMR studies of cellular and tissue metabolism in the 1970s,¹ in 1980 it was reported that the use of an unusual type of radiofrequency coil, termed a surface coil (see *Surface and Other Local Coils for In Vivo Studies*), provided a simple and effective means of probing skeletal muscle and brain metabolism noninvasively in small animals.² The ^{31}P spectra that were obtained in these studies (Figure 1) illustrate the type of information that is provided by ^{31}P NMR. The spectra of skeletal muscle and brain include ^{31}P signals from ATP, phosphocreatine (PCr), and inorganic phosphate (Pi), metabolites that play central roles in energy metabolism. In addition to measuring the relative concentrations of these metabolites, it is also possible to determine the intracellular pH from the chemical shift of the inorganic phosphate signal. A number of interesting points emerged from these surface coil studies. For example, the ratio of phosphocreatine to ATP was on the high side of values commonly obtained using invasive rapid freezing techniques, while the concentrations of inorganic phosphate and of free cytoplasmic ADP were lower than those measured with invasive techniques.

While the measurement of relative concentrations often provides an adequate basis for interpretation, there is increasing emphasis on the determination of absolute concentrations. A number of studies have shown that NMR and freeze clamping measurements tend to give similar values for tissue ATP concentrations.³ In some cases, however, the two types of measurement may differ somewhat because of the presence of NMR-invisible ATP pools. Also, comparison of the two types

of measurement is complicated by the fact that nucleotides other than ATP can make contributions to the triphosphate signals; in recognition of this, these signals are sometimes labeled NTP rather than ATP. In contrast to these ATP observations, the concentrations of ADP and inorganic phosphate that have been measured in various tissues using noninvasive NMR methods are often much lower than those measured by analysis of tissue extracts.^{4–6} These discrepancies in the measurements of ADP and inorganic phosphate could reflect the presence of NMR-invisible intracellular fractions, resulting from tight binding to macromolecules or perhaps from sequestration within certain intracellular compartments, including the mitochondria. Alternatively, in some cases they may reflect an unavoidable breakdown of high-energy phosphates in invasive measurements, for example in human biopsy analyses where there is an inevitable delay between removal and freezing of the sample. Regardless of the precise explanation for the differences between these NMR and chemical measurements, the low levels of free inorganic phosphate and ADP have important kinetic and thermodynamic implications; in particular, these findings strongly influence our understanding of those reactions that are subject to control by inorganic phosphate and ADP.⁷

^{31}P MRS provides an excellent experimental approach to the investigation of changes in energy metabolism associated with impaired oxygen delivery, as in ischemia or hypoxia. Metabolic changes can be monitored sequentially in a single animal, for example throughout a period of ischemia and subsequent reperfusion, offering considerable advances over invasive methods of analysis. One of the main areas of interest is the evaluation of agents or procedures that may protect

Figure 1 ^{31}P spectra obtained at 74 MHz showing signals from the α -, β -, and γ -phosphates of ATP, phosphocreatine (PCr), and inorganic phosphate (Pi) in (a) skeletal muscle and (b) the brain of an anesthetized rat. The brain spectrum also shows signals from phosphomonoesters (6–8 ppm) and phosphodiester (2–4 ppm). against the damaging consequences of inadequate oxygen supply. This is of relevance to conditions such as stroke, to methods used for the preservation of organs prior to transplantation, and to cardioplegic techniques for use during open heart surgery. To exemplify this approach, a later section of this article describes some studies of experimental stroke.

Extensive studies have also been carried out of the metabolic changes that are associated with muscular exercise. While a number of such studies have been carried out in animals, the advantages of spectroscopy are most apparent for investigations in humans, where there are obvious benefits over biopsy procedures (see *Whole Body Studies: Impact of MRS*). The large changes in energy demand and in the concentrations of the energy metabolites make it reasonable to expect that metabolites such as ADP should play a key role in the control of energy metabolism in skeletal muscle, and numerous studies have indicated that this is so. However, it is less obvious that this should be the case for other tissues such as cardiac muscle, liver, and brain which do not have such extensive variations in energy demand. Indeed, ^{31}P NMR studies of the heart (discussed more fully below), brain, and kidney have shown little correlation between the rate of oxidative phosphorylation in the steady state and the cytoplasmic concentrations of ADP, inorganic phosphate, and ATP.⁷ This does not mean that these metabolites no longer have the capacity to control oxidative phosphorylation in these tissues. However, it does suggest that, at least under the conditions of these particular studies, there are other factors, including substrate and oxygen delivery, that presumably have a stronger influence on the regulation of oxidative phosphorylation.

It is difficult to measure free ADP directly from ^{31}P spectra, partly because its signals overlap with the much larger signals from ATP, but also because it is apparent that, even if overlap were not a problem, the free ADP is commonly present at such low concentrations that its signals would not be visible above the noise. The evidence for this is obtained by making use of the creatine kinase equilibrium, which permits the concentration of free ADP to be calculated on the basis of the known concentrations of the other creatine kinase reactants. While this method is feasible for skeletal muscle, cardiac muscle, and brain, it cannot be used for tissues that do not express significant amounts of creatine kinase, such as liver and kidney. An interesting means of circumventing this problem has been described by Brosnan et al.⁸ who used the transgenic mouse technique to express high levels of creatine kinase in the liver. They were thus able to show that the free ADP in the liver was about $60\ \mu\text{mol g}^{-1}$ wet weight. This is similar to the value previously determined by Veech et al.⁹ on the basis of similar arguments involving enzymes that are believed to catalyze reactions that are near to equilibrium. Such transgenic models could clearly contribute significantly to our understanding of tissue metabolism and its control.

^{31}P NMR can make further contributions to our understanding of the kinetic and thermodynamics of oxidative phosphorylation, through its ability to monitor the unidirectional flux between ATP and inorganic phosphate in intact tissues. This measurement can be achieved by magnetization transfer techniques, in an analogous manner to the measurement of creatine kinase activity, and a particularly extensive series of studies has been carried out on cardiac muscle.¹⁰

These magnetization transfer studies of cardiac muscle were carried out on isolated perfused preparations. The study of cardiac muscle in vivo is a lot more difficult, partly because of the effects of motion, and also because blood can contribute significant amounts of signal, making measurements based on the phosphomonoester and inorganic phosphate signals particularly problematical. Some of the problems can be circumvented by the use of surgical procedures enabling the radiofrequency coil to be positioned adjacent to the region of interest. A number of such studies have been carried out on the dog heart in vivo. For example, a series of ^{31}P studies has been carried out examining the relationship between workload and phosphorus energy metabolites. It was found that the concentration of ADP and the phosphocreatine/ATP ratio in the heart did not change significantly despite an almost fourfold change in ATP hydrolysis, as estimated from the myocardial oxygen consumption.¹¹ It was subsequently found that there were no significant changes in ATP, ADP, phosphocreatine, or inorganic phosphate until the workload apparently outstripped the ability of the heart to produce ATP, because of limitations either in coronary blood flow or in oxidative phosphorylation capacity.¹² As discussed above, these findings are relevant to our understanding of metabolic control in the heart.

The spectral contributions from blood, which as mentioned above cause problems with observations based on the inorganic phosphate signal (including measurements of myocardial pH), can be eliminated or at least greatly reduced by using appropriate localization techniques. For example, Robitaille et al.¹³ described the use of one-dimensional spectroscopic imaging in conjunction with an implanted surface coil to detect the transmural metabolite distribution in the dog heart. Amongst their findings, they noted that their measured pH value of 7.0–7.1 was in agreement with measurements on perfused hearts, and suggested that in some in vivo studies the pH might have been overestimated due to the contributions of 2,3-diphosphoglycerate and inorganic phosphate from the blood.

3 ^1H MRS AND BRAIN METABOLISM

Following earlier studies of metabolism in red blood cells,¹⁴ the first high-resolution ^1H spectra of intact animals were reported by Behar et al.¹⁵ In their studies of the rat brain, they were able to observe ^1H signals from a number of metabolites, including *N*-acetylaspartate, creatine + phosphocreatine, and choline-containing compounds, and they demonstrated an increase in the lactate signal on hypoxia, with a return to normal on subsequent oxygenation (Figure 2). Numerous technical developments followed, and ^1H MRS is now extensively used for the noninvasive detection of human brain metabolites. The range of metabolite signals that has been unequivocally identified by ^1H MRS has widened considerably, and a variety of animal models of disease have shown the presence of unusually high signals from specific metabolites. For example, histidine has been detected in mice with histidinemia,¹⁶ elevated glutamine has been seen in hyperammonemic rats,^{17–19} unusually high concentrations of choline-containing compounds (and in particular betaine) are present in animal models of multiple sclerosis,^{20,21} and high levels of γ -aminobutyrate (GABA) have been observed in rats treated with anticonvul-

sants that act as inhibitors of GABA transaminase.^{22,23} Studies of this type have pointed the way forward to analogous investigations of disordered cerebral metabolism in man; they can also aid interpretation and assignment of clinical spectra. In addition, of course, they can highlight potential pitfalls in interpretation. For example, in clinical spectroscopy the assignment of signals to brain lipids may need to be treated with some caution, in view of the demonstration that certain brain proteins can give rise to peaks that show some similarities with lipid signals.^{24,25}

A number of animal studies, including some of those mentioned above, have shown that there could be many conditions in which the ^1H spectra are more responsive than ^{31}P signals to brain disease. However, in relating animal studies to clinical investigations, it must be appreciated that many animal models are studied in the acute phase, whereas the majority of clinical cases are investigated in the subacute or chronic phase. This is just one reason why some degree of caution must be exercised in making comparisons between studies of animal models and of man. One metabolite that is of particular relevance in this context is *N*-acetylaspartate. Several lines of evidence suggest that almost all of the *N*-acetylaspartate within the brain is neuronal, and so in clinical studies a reduction in the *N*-acetylaspartate signal is commonly interpreted in terms of neuronal loss or damage.²⁶ This interpretation is consistent with the spectral changes that have been observed in a number of disorders for which neuronal loss can be expected, including stroke, gliomas, AIDS, and epilepsy (see *Brain Infection and Degenerative Disease Studied by Proton MRS*). However, extensive loss of *N*-acetylaspartate is less commonly observed in animal models, primarily because the pathological processes resulting in such loss may have a timescale of many hours or days, whereas the animal models are often studied in the acute phase. Thus in ^1H studies of animal stroke models, the emphasis has tended to be more on the detection of acute changes in lactate than on chronic changes in *N*-acetylaspartate. In more chronic animal models, a major loss of *N*-acetylaspartate has indeed been observed, and in kainate-induced status epilepticus this loss has been found to correlate well with neuronal injury.²⁷

4 ^{13}C MRS AND INTERMEDIARY METABOLISM

The natural abundance of ^{13}C is only 1.1%, and this has led to the emergence of two categories of investigation. In one category, the compounds of interest are present at sufficiently high concentrations to permit detection without ^{13}C labeling. These natural abundance studies are primarily of storage compounds, in particular glycogen, since these tend to be present in the appropriate concentration range. In the early 1980s, it was reported that glycogen gives a well-resolved ^{13}C NMR spectrum in which the carbons are almost completely NMR-visible.²⁸ This was somewhat surprising in view of the fact that large molecules with relatively little mobility tend to give very broad signals. Presumably, glycogen has a high degree of internal mobility, as a result of which its carbons give fairly narrow signals. The high concentration of glycogen in liver and muscle means that its ^{13}C signals can be detected in these tissues without any need for isotopic enrichment. In common

Figure 2 ^1H NMR spectra obtained at 360 MHz from the rat brain in vivo, showing the time course of lactate production and clearance during hypoxia and recovery. Phosphocreatine and creatine (PCr/Cr), *N*-acetylaspartate (N-Ac-Asp), and lactate (Lac) signals are labeled. Conditions were as follows: a, normoxic, 25% O_2 ; b, hypoxic, 5 min after administration of 4% O_2 ; c, after 17 min at 4% O_2 ; d, recovery, 14 min after administration of 25% O_2 ; e, after 41 min at 25% O_2 . (Reproduced with permission from Behar et al., *Proc. Natl. Acad. Sci. USA*, 1983, **80**, 4945)

with other developments in spectroscopy, the main applications for the detection of glycogen may well prove to be in man.

The second category of ^{13}C studies exploits the use of ^{13}C -labeling for the investigation of specific metabolic pathways. For example, Kunnecke et al.²⁹ have investigated the metabolism of $[1,2-^{13}\text{C}_2]\text{glucose}$ and of multiply-labeled 3-hydroxybutyrate in rat brain, obtaining spectra both in vivo and in vitro. Figure 3 shows in vivo ^{13}C spectra of rat brain before infusion (a) and during infusion of each of the two substrates (b

Figure 3 ^{13}C NMR spectra of rat brain obtained at 20 MHz in vivo before (a) and during the infusion of $[\text{U-}^{13}\text{C}_4]\text{3-hydroxybutyrate}$ (b), or $[1,2\text{-}^{13}\text{C}_2]\text{glucose}$ (c). The insets show the spectra of $[\text{U-}^{13}\text{C}_4]\text{3-hydroxybutyrate}$ (b) and $[1,2\text{-}^{13}\text{C}_2]\text{glucose}$ (c) in saline solution. (Reproduced with permission from Kunnecke et al., *NMR Biomed.*, 1993, 6, 264)

and c), while Figure 4 shows the corresponding spectra obtained from perchloric acid extracts of the brain. Analysis of the spin-coupling patterns in such spectra provides detailed information about many aspects of cerebral metabolism, including the pathways of glutamate, glutamine, and GABA synthesis, and reveals various features of metabolic compartmentation that can readily be attributed to the differing metabolic characteristics of neurons and glial cells. These studies can also contribute to our understanding of the role of *N*-acetylaspartate, which was referred to above in relation to ^1H MRS studies of the brain. In particular, it was found that while free aspartate is ^{13}C -enriched to a similar extent as glutamate and glutamine, the labeling of the aspartyl moiety of *N*-acetylaspartate remained at the natural abundance level. In contrast, the acetyl moiety of *N*-acetylaspartate was significantly enriched, lending further support to the view that this metabolite may act as an acetyl carrier or as a storage form of acetyl-CoA.

An alternative technical approach exploits the influence of the ^{13}C spin on the signals from neighboring protons. For example, the CH_3 protons of lactate are split into a doublet if the C3 carbon is ^{13}C -labeled, and the detection of such splitting in ^1H spectra has formed the basis for demonstrating turnover of brain lactate in human stroke. As an extension of this indirect approach to the detection of ^{13}C label, the ^1H sig-

nals can be detected with and without ^{13}C -decoupling, and this provides a means of measuring fractional enrichment of the ^{13}C label. Such proton-observe-carbon-edit methods³⁰ have been used to measure the rate of label entry from $[1\text{-}^{13}\text{C}]\text{glucose}$ into glutamate. Since the glucose carbon is incorporated into glutamate by rapid exchange with the tricarboxylic acid cycle (TCA) intermediate α -ketoglutarate, it is possible to use the rate of glutamate labeling to obtain an estimate of the TCA cycle activity. The method has now been extended from animal studies to humans. Since ^1H MRS is intrinsically more sensitive than ^{13}C MRS, it is likely that this type of approach will greatly extend the applicability of ^{13}C -labeling studies in vivo. These ^{13}C studies, and in particular their applications to humans, are discussed extensively in the article on *Brain MRS of Human Subjects*.

5 MRS AND CEREBRAL ISCHEMIA

Ischemia refers to reduced blood flow, and has been defined as 'blood flow... too low to supply enough oxygen to support cellular function'.^{31,32} One question that arises is how well one can define a threshold value for cerebral blood flow, above which energy supply is sufficient but below which energy failure ensues. The precise relationship between flow and energy metabolism has been difficult to establish because of problems in making concurrent measurements of flow and metabolism in vivo in a single animal as a function of time. These problems can be overcome with the aid of MRS measurements.

The combination of ^1H and ^{31}P spectroscopy, together with simultaneous measurements of regional cerebral blood flow using the hydrogen clearance technique, has demonstrated that major changes in energy metabolites occur in the gerbil brain when the flow falls from control values of about 60 mL per 100 g per min to about 20 mL per 100 g per min or below.³³ These changes reflect the characteristic metabolic features of energy failure; that is, there is a decrease in high-energy phosphates and intracellular pH, and an increase in inorganic phosphate and lactate. The flow value of 20 mL per 100 g per min is similar to that at which, in a variety of species (including man), electrical activity ceases, and is also similar to the flow level at which water accumulates in the gerbil brain. These results therefore provide evidence suggesting that the thresholds for electrical function and edema are a direct consequence of energy failure. A model such as this could also prove to be useful when examining pharmaceuticals or other forms of therapy that may influence flow and/or metabolism. For example, one might anticipate that a treatment could be beneficial if it lowers the threshold flow value from 20 to, say, 10 mL per 100 g per min, as this would imply that the brain can tolerate lower flow values without undergoing energy failure. To illustrate this point, it was shown that the decline in energy status at reduced flow values is less severe under hypothermic (30°C) conditions than at normal body temperature, consistent with a protective effect of hypothermia.³⁴

Ischemia is also associated with failure of the transmembrane ionic pumps, and this aspect of energy failure can be investigated with ^{23}Na NMR. As discussed in the article *Cation Movements across Cell Walls of Intact Tissues Using*

Figure 4 ^{13}C NMR spectra obtained at 100 MHz from perchloric acid extracts of rat brains after the infusion of saline solution (a), $[\text{U-}^{13}\text{C}_4]\text{3-hydroxybutyrate}$ (b), and $[1,2\text{-}^{13}\text{C}_2]\text{glucose}$ (c). Only the aliphatic and carboxylic regions of the spectra are shown. (Reproduced with permission from Kunnecke et al., *NMR Biomed.*, 1993, **6**, 264, where the numerous spectral assignments are given)

MRS, the ^{23}Na signals of intracellular and extracellular Na^+ ions differ in their relaxation properties, and this provides a means of exploring changes in the distribution of Na^+ ions across the cell membrane. Thus the relationship of ion homeostasis to tissue energetics can be carried out by combining ^{31}P with ^{23}Na NMR.^{35–37} For example, one study showed that upon production of cerebral ischemia there is a delay of approximately 2 min before the ATP level begins to fall and the intracellular Na^+ begins to rise.³⁷ These findings, together with the flow thresholds that have been observed for energy failure, are relevant to observations that have been made in recent years using diffusion-weighted MRI, a technique that shows remarkable sensitivity to early events in cerebral ischemia.^{38,39} On the basis of the relationships between the spectroscopy and diffusion-weighted imaging findings, it appears that the diffusion-weighted imaging changes observed early after the onset of ischemia are sensitive to the disruption of tissue energy metabolism or to a consequence of this disruption, including water movements associated with loss of ion homeostasis. This has raised the interesting possibility of using diffusion-weighted imaging to visualize regions of compromised energy metabolism in man, with the spatial resolution characteristic of

MRI; i.e. with much superior spatial resolution to that provided by ^{31}P or ^1H MRS of energy metabolites.

6 GENERAL DISCUSSION

While the focus of attention in MRS studies is inevitably moving towards noninvasive studies of tissue metabolism in man, it is apparent that studies of animal models of disease will continue to complement and aid interpretation of clinical observations. The above studies serve to illustrate the central role that animal studies can play in the investigation of tissue biochemistry and pathophysiology; they also show the importance of combining these MRS studies with *in vitro* analyses of tissue extracts, and with MRI investigations. It is this type of integrated approach that offers much of the excitement for the future.

Animal Models of Stroke Studied by MRI

Mark F. Lythgoe and David G. Gadian

Royal College of Surgeons Unit of Biophysics, Institute of Child Health, London, UK

1 INTRODUCTION

This chapter describes the development and adaptation of the various animal models of stroke for use with MRI and MRS. The evolution of animal models for use with MR systems has been driven by the introduction of new MR techniques and by the increasing awareness of the role of these techniques in investigating the pathophysiology and treatment of stroke.

Early research in this area used *in vitro* MRS of cortical and white matter tissue to investigate cerebral edema and demonstrated the potential applicability of MR for the noninvasive detection of human stroke.¹ With the advent of imaging systems in the early 1980s and the development of animal models for *in vivo* research, regional changes in T_1 and T_2 were observed in animal models several hours following the initial insult.² During this time, *in vivo* MRS was used to follow changes in high-energy phosphates, inorganic phosphate, intracellular pH, lactate, and changes in Na^+ distribution in various animal models of ischemia, anoxia, and hypoxia.³ From these early experiments it became apparent that NMR, together with other techniques such as specific gravity measurements or histology, is well suited for use in the investigation and

characterization of stroke.⁴ Later in the 1980s, more elaborate experiments were designed, permitting the simultaneous acquisition of cerebral blood flow (CBF) and MRS data for the determination of CBF thresholds in cerebral ischemia.⁵ These experiments were carried out by producing graded ischemia during the MR investigation using a remote-controlled method for gradually reducing the CBF through a series of desired levels. This novel model was subsequently used to demonstrate the relationship between diffusion-weighted imaging, energy metabolism, and CBF (Figure 1).^{6,7} Even though MR systems place constraints on methodology through the confined space of the magnet bore, simultaneous physiological monitoring of electrical activity, blood gases, and blood pressure was found to be feasible.⁸

The introduction of new MRI techniques such as diffusion-weighted imaging⁹ which allows the investigation of a stroke within minutes of the initial event, led to the modification of animal models to take advantage of this information about hyperacute changes. This type of animal model required remote-controlled access, that is, the ability to modulate the animal physiology from outside the MR system; this is perhaps the most challenging of adaptations (see Section 3).^{10,11} Recent developments include the application of optical techniques for noninvasive cerebral metabolic monitoring and histological studies in conjunction with MR.¹² Near-infrared spectroscopy can be used to monitor hemoglobin oxygenation, the oxidation state of cytochromes, and cerebral blood volume. Laser Doppler flowmetry is used for the noninvasive measurement of CBF, and invasive bioluminescence techniques may be used to monitor metabolic disturbances. All of these methods have been interfaced with animal models of stroke and MR.^{13–15}

Since the mid-1980s comprehensive reviews have described the numerous possible animal models in the investigation of cerebral ischemia.^{16–20} Further, the relevance of these animal models to human disease has also been considered;^{21–23} consequently, this area is not a focus for discussion in this article.

Figure 1 Remote-controlled graded ischemia produced using a snare system around both common carotid arteries in a Mongolian gerbil model. This animal model was developed to investigate the relationship between cerebral blood flow (CBF), measured with a H_2 clearance technique, diffusion-weighted MRI, and energy metabolism. CBF thresholds are similar for diffusion and for changes in $\text{Pi}/(\text{PCr} + \text{Pi})$. This suggests that the depletion of high-energy phosphates, leading to energy failure and an inevitable accumulation of intracellular osmotically obliged water (cytotoxic edema), results in a diffusion change through the redistribution of the water molecules. (Kindly provided by Dr Albert Busza)

The following sections contain an overview of the most widely used small animal models for MR investigations of stroke, including a discussion of the early work and subsequent modifications of these techniques for MR use.

2 FROM THE BENCH TO THE MR SYSTEM

Experimental models of cerebral ischemia may be broadly classified into global or focal models, which may, in turn, be permanent or reversible in nature. In deciding which animal model should be used to test a hypothesis, the MR researcher must take into account issues that may not be a consideration when experimenting 'on the bench'. When choosing an animal model, the investigator must consider aspects of the MR system such as the bore size of the magnet and access to the animal once it is positioned in the magnet. Another consideration is whether the magnet is horizontal or vertical, which may influence the physiology of the animal, although this is becoming less of an issue as more and more researchers use dedicated horizontal systems. Issues of temperature and its control, together with the physiological monitoring and administration of anesthetics, can also be difficult to address and must be taken into account during experimental design.

Once the choices between global and focal models, and between different animal species have been made, the issue of whether to induce the insult outside the magnet arises and whether the insult is to be treated or reversed from within the magnet. Initial experimental MR studies of stroke required that, following acquisition of the preischemia data, the animal was removed from the magnet so that the lesion could be induced on the bench, after which the animal was then replaced and the post-insult data were acquired. Improvements in design that permit remote access have allowed the investigation of the pathological consequences of the stroke immediately following the insult and have allowed direct comparison with control images without the need for image registration. This, of course, is not possible with all procedures, but the advantages are clear if remote access is achieved.

To acquire data within the MR scanner, the animal should be immobilized in a nonmagnetic probe with ear and bite bars rather like a stereotactic head holder, allowing the head to be positioned relative to the gradient coils to attain the correct imaging slice or region of interest. In MR magnets with a small bore, the use of ear and bite bars may not be possible, in which case the skull may be glued directly to the probe to reduce movement artefacts.²⁴ Temperature control is commonly attained through the use of warm air blown over the animal, an electrically heated mat, or warm water jacket or mat. Animals are readily anesthetized by administration of anesthetics through a nose cone for spontaneously breathing rats, by intraperitoneal injection, or by mechanical ventilation. Physiological monitoring of electrocardiographs (ECG) and respiration rate may be performed simultaneously using implanted chest electrodes.²⁵ Blood pressure is conventionally monitored using an intra-arterial line or, more recently, a piezo-electric pulse transducer.²⁶ Intravenous lines may be inserted for blood gas measurements or administration of drugs. Nonmagnetic graphite electrodes, which reduce susceptibility effects, may be used for electroencephalography (EEG).¹¹

3 FOCAL ISCHEMIA

A number of experimental models of focal ischemia have been developed, including permanent, reversible, and partial occlusions (Table 1).

3.1 Permanent Middle Cerebral Artery Occlusion

Rats with permanent occlusion of the middle cerebral artery (MCA) are frequently used for exploring the pathogenesis of infarction and for the evaluation of new therapeutic agents.⁵⁴ In 1975, Robinson et al. developed a model of MCA occlusion in the rat in which the MCA was coagulated distal to the rhinal fissure, the procedure being performed through a craniotomy.⁵⁵ To improve the reproducibility of this model, Tamura et al. adopted a subtemporal approach in which the proximal MCA was occluded between the rhinal branch and the lateral striate arteries in Sprague-Dawley rats.³¹ A less surgically demanding procedure was described by Chen et al., involving a more distal occlusion of the MCA above the rhinal fissure, coupled with permanent ipsilateral and temporary contralateral occlusion of the common carotid arteries (CCA).⁵⁶ Several modifications of the above model have been described in conjunction with occlusion of the MCA to increase reproducibility further, such as MCA occlusion following a brief period of hypotension⁵⁷ or permanent occlusion of the ipsilateral CCA.⁵⁸ The advantages of this type of model include its reproducible nature¹⁶ and the ease of adaptation for MR use. However, as the occlusion is performed on the bench, the early stage of ischemia is lost because of the time taken to place the animal in the MR system from the bench, and the shimming and MR setup period. Permanent occlusion of the MCA may also be performed using the intraluminal suture approach, which has been used extensively with MR, as described below (Figure 2).⁵⁹

3.2 Reversible Middle Cerebral Artery Occlusion

Permanent MCA occlusion models do not permit the investigator to monitor the effects of reperfusion following the initial insult. To address this problem, experimenters have developed a number of methods for occluding and reperusing the MCA.

In 1985, Shigeno et al. placed a snare ligature around the stem of the MCA in a rat model, just distal to the lenticulostriate branches, and by pulling and releasing the thread, they occluded then reperused the MCA.⁶⁰ This technique and many of the above are very invasive, requiring craniotomy, durotomy, and arachnoid incision, with associated drainage of cerebrospinal fluid and altered intracranial pressure. The next section describes a rat model of reversible MCA occlusion that avoids many of the above disadvantages. This type of model is now used with MR to investigate the early changes following cerebral ischemia.

In 1986, Koizumi et al. developed a new reversible focal ischemic model.²⁷ The MCA was occluded by a silicone rubber cylinder attached to a thread inserted through the internal carotid artery in Wistar rats. Recirculation was accomplished by pulling the thread out of the artery. This model has the advantage of avoiding craniotomy and has an important role in MR investigations of ischemia. The intraluminal thread method of

Suture, intraluminal thread (nylon monofilament), which may be coated and retractable; remote, insult may be performed from outside the magnet; rev, mechanism for insult may be reversed to control state; graded, insult may be performed in a controlled graded fashion; coagulation, electro-coagulation of vessel.

occlusion was later modified by Zea Longa et al. using a blunted nylon monofilament, in an attempt to increase reproducibility.⁶¹

In one study comparing these two techniques, it was suggested that there were differences in the levels of reduced CBF on occlusion, and that the Koizumi method was more reliable than that of Zea Longa.⁶² However, other investigators have not supported these conclusions. The discussions for these variations focused on the degree of silicone coating of the thread, the filament size and length, and the body weight of animals.^{63,64} It is interesting to note that, when comparing two uncoated 4-0 nylon monofilaments from different manufacturers, subtle differences in material and diameter resulted in variations in the final infarct size following MCA occlusion.⁶⁵ There is still much debate as to whether to coat the suture and what coating to use; one investigator has suggested that a simple coating of poly-*l*-lysine can reduce interanimal variability and increase infarct size.⁶⁶

Two recent studies have investigated, at some length, the intraluminal suture model. Li et al., using a silicone-coated 4-0 nylon occluder adapted for remote occlusion during MRI (see below), achieved successful occlusions in 88% of animals without subarachnoid hemorrhage.⁶⁷ The failures included preocclusion damage (1/67), occluding device sliding out of the outer holding catheter (1/67), no occlusion (2/67), and arterial perforation (4/67). The other critical evaluation of the suture method, by Schmid-Elsaesser et al., indicated that a 4-0 silicone-coated suture, when compared with a 3-0 uncoated suture, produced less subarachnoid haemorrhage (8% compared

with 30%).⁶⁸ However, with both these types of suture, premature reperfusion occurred in the first minutes of MCA occlusion in approximately 25% of studies, and this contributed to variability in the lesion size. Consequently, institutions using equivalent methods observe different lesion variability, which indicates the difficulty with these methods. One cannot overestimate the lengths to which a researcher must go in order to standardize the intraluminal MCA occlusion technique.

3.3 Use of Reversible Middle Cerebral Artery Occlusion with MRI

The advantage of the suture technique is that it allows remote-controlled occlusion (Figure 2) and reperfusion of the MCA from outside the magnet. Remote occlusion is essential to investigate the hyperacute MR changes postocclusion and also to allow a direct comparison of pre- and postocclusion image data.^{67,69} This technique was adapted for MR use by Roussel et al. using a 2×0.25 mm silicon embolus on a nylon thread,⁶⁹ by Kohno et al. using a 3-0 monofilament coated with glue,¹¹ and, more recently, by Li et al. using a silicon-coated 4-0 monofilament.⁶⁷ This early work was performed in large horizontal bore imaging magnets and has been further modified for remote MCA occlusion studies in a 5 cm diameter bore vertical 8.5 T magnet.⁵⁹ This is not a trivial experiment but, as shown by Li et al., successful occlusion can be achieved in 88% of animals studied.⁶⁷

Figure 2 Remote-controlled permanent intraluminal suture occlusion of the middle cerebral artery allows MR images to be acquired throughout the acute period. (a) A map of cerebral blood flow (CBF) (measured using arterial spin labeling) with reduced flow in the occluded side (acquired 12 min postocclusion). (b) The apparent diffusion coefficient of water (25 min postocclusion) with a region of reduced diffusion indicating the area of cytotoxic edema. (c) A T_2 map (1 min postocclusion) with a region of reduced T_2 . (d) A T_1 map (5 min postocclusion), with a region of increased T_1 . (e) Schematic representation of the three main areas: 'normal tissue'; 'diffusion and perfusion mismatch area', with reduced CBF but normal diffusion; and 'severely affected area', in which both the CBF and diffusion were significantly reduced. (Kindly provided by Mr Fernando Calamante)

3.4 Incomplete or Partial Occlusion

Models of focal oligemia are not common, although they are finding increasing use in the investigation of the pathophysiology of penumbra, in which regions of oligemic misery perfusion are present.⁷⁰ The aim of these experimental models is to produce a large focal lesion in which the CBF is moderately reduced throughout the MCA territory (see Table 4). The degree of reduction in CBF is dependent upon the method used and the degree of stenosis or partial occlusion. In 1994, Derugin et al. developed a reversible MCA stenosis.⁸⁵ More recently, a rat model was developed for MR use in which a combination of hypotension (induced by placing the rat vertically) and electrocoagulation of the distal MCA produced a

focal hypoperfusion lesion.⁸⁶ However, only the first of these models allows reperfusion to take place and neither permits occlusion from outside an MRI scanner to observe the hyperacute phase following occlusion. To avoid these problems, Thomas et al. developed a model based on the intraluminal suture method that used an undersize suture to produce a partial obstruction of the MCA and a moderate reduction in CBF throughout the MCA territory (Figure 3).⁸⁷

3.5 Focal Lesion: Other Methods

Further methods of inducing focal ischemia that avoid a craniotomy include injection of homologous blood clot fragments⁴⁷ and intraluminal occlusion with a silicon cylinder.^{39,42} Another method for producing focal infarction is the injection of rose bengal dye, followed by photochemical activation to induce focal thrombosis and cerebral ischemia.⁴⁸ This model has the advantage of being relatively noninvasive, as well as providing several cerebral locations for the placement of the lesion, although it does result in microvascular injury. Focal cerebral ischemia can also be induced using a local application of endothelin-1, a vasoconstrictive agent, which produces a blood flow decrease with a half-time of 45 to 60 min.³⁵ An animal model of subarachnoid hemorrhage has been produced using modification of the intraluminal suture model, which allows perforation of the circle of Willis and subsequent production of the hemorrhage (Table 3). This technique may be performed remotely and therefore monitored from the hyperacute phase onwards using MR.^{88,89}

4 GLOBAL ISCHEMIA

Cardiac arrest has been extensively employed for the study of the pathological consequences of global ischemia and reperfusion (see Table 2).²⁰ Fischer et al. have extended this work for MR and demonstrated the feasibility of resuscitation following cardiac arrest within the magnet, thus enabling them to follow cerebral events during reperfusion.⁸³ As well as the cardiac arrest models, there are essentially three commonly used small animal models of global cerebral ischemia for use with MR, two in the rat and one in the gerbil. The four-vessel occlusion model in the rat produces global ischemia, while the other two models induce a bilateral forebrain ischemia. Global insults may also have both a hypoxic and ischemic component. With the aim of modeling human birth asphyxia, Thornton et al. have recently described the temporal and anatomical variation of the cerebral apparent diffusion coefficient (ADC) of water, following a hypoxic/ischemic insult in a piglet model (Figure 4).⁹²

4.1 Four-vessel Occlusion Model

In 1979, Pulsinelli and Brierley introduced the four-vessel occlusion model of reversible ischemia in rats.⁷⁴ Modifications by the same group increased the proportion of successful studies.⁹⁵ Briefly, on the day before the experiment, atraumatic clasps are placed loosely around both CCAs, and the vertebral arteries are electrocauterized through the foramen alar in the first cervical vertebra. Global ischemia is induced by tightening the sutures around the CCAs. A period of between 10 and 30

Figure 3 Intraluminal suture to produce partial and complete middle cerebral artery occlusion (MCAO). (a) Conventional MCAO in the rat using a 0.24 mm diameter nylon monofilament. Following occlusion there is a concomitant CBF and apparent diffusion coefficient (ADC) decline. (b,c) Partial occlusion of the middle cerebral artery using an undersized embolus (0.2 mm) with a bullet-shaped tip induces a moderate CBF decrease without ADC decrease

min of ischemia, followed by reperfusion, produces cell changes that provide evidence of selective vulnerability and delayed neuronal damage.⁹⁶ This technique has been used quite extensively with MR for both single and repeated occlusions,⁸¹ and also to produce graded ischemia.⁸²

4.2 Gerbil Bilateral Common Carotid Occlusion Model

In most animals, as in humans, occlusion of the CCAs will not produce ischemia. In 1966, Levin and Payen demonstrated

that in gerbils there was an anomaly in the circle of Willis such that unilateral occlusion of the CCAs resulted in ipsilateral forebrain ischemia in 40% of the animals.³⁶ The anomaly involved the absence of the posterior communicating arteries, which connect the anterior and posterior circulation to the brain. Subsequently, it was demonstrated that almost all gerbils exhibited neurological signs of ischemia if both CCAs were ligated. This method of occlusion has been used for both single (Figure 5)⁹⁷ and graded⁶ occlusion MR experiments. Early work using this model demonstrated regions of delayed tissue

Table 2 Global models in which cerebral blood flow is reduced

Method of occlusion	Species	Remote/reversible	References	
			Non-MR models	MR examples
Occlusion of the common carotid arteries				
Bilateral, remote	Gerbil	Remote/rev	71	77
Bilateral, graded	Gerbil	Remote/rev	71	7
Plus hypotension	Cat	Remote/rev	72	78
Plus hypoxia	Neonatal pig	Remote/rev		79
Occlusion of innominate and left subclavian, remote	Cat	Remote/rev	73	80
Occlusion of common carotid and vertebral arteries

See Table 1 for definition of terms.

damage following a brief period of bilateral CCA occlusion.⁹⁸ More recently, early subtle changes in diffusion imaging have been observed in regions known to present with delayed damage, indicating the gradual evolution of these lesions (Figure 6; Table 3).^{99–101}

4.3 Rat Two-vessel Occlusion Model

This type of model is not commonly used by MR researchers, although it is technically easier to perform than the four-vessel model. Due to the intact circle of Willis in the rat, bilateral occlusion of the CCAs must be combined with systemic hypotension to produce reversible ischemia.¹⁸ Hypotension is induced by bleeding¹⁰² or with the administration of trimethaphan or phentramine.¹⁰³ This model is influenced by the need to monitor and correct for alterations

in systemic hypotension, which may limit its applicability to MR studies.

4.4 Graded Global Ischemia

The methods for occlusion that have been mentioned so far do not provide any flexibility in the level of reduction of CBF. The degree of ischemia is primarily dependent on the vessel occluded, the quality of occlusion, and the collateral supply to that region. Most types of intervention give little or no control over the level of the induced ischemia. Controllable graded ischemia, however, allows investigation of cerebral tissue at the desired level of CBF. Using a gerbil model, Allen et al. have placed adjustable snares around the CCAs that can be tightened to decrease the internal diameter of the CCAs, thereby reducing the flow to the forebrain.⁶ Forebrain blood

Figure 5 Forebrain ischemia induced for 5 min via remote-controlled bilateral carotid artery occlusion in a gerbil. Noninvasive MR measurement of cerebral blood flow using an arterial spin labeling technique demonstrated a prolonged and delayed hypoperfusion following reperfusion. (Kindly provided by Dr Gaby Pell)

Figure 6 Diffusion (apparent diffusion coefficient, ADC) images over 10 h following 5 min of bilateral common carotid artery occlusion in three gerbils; one representative image is shown. The region of diffusion change in the image is localized to the lateral portion of the striatum, which is an area known to present with delayed tissue damage.¹⁰¹ In this region a gradual diffusion decrease is observed throughout the reperfusion period

flows ranging from 80 to 8 ml min⁻¹ per 100 g tissue are attainable with this method (see Figure 1).

5 CONCLUSION

Adaptation of some animal models for use with MRI is a relatively simple practice, while for others that require remote access it is technically more demanding. The ability of MR to follow time courses in single animals has promoted the development of new animal models in which data can be acquired before and after the insult without removing the animal from the magnet. The development of a range of physiological MRI techniques, including diffusion, perfusion and T_2^* -weighted imaging, as well as various MRS approaches, provides new opportunities for understanding the evolving pathophysiology of lesions in these models and for evaluating novel forms of therapy.

1 INTRODUCTION

1.1 Historical Perspective

The full potential for the use of high resolution NMR spectroscopy as applied to the study of body fluids has only become apparent in the last decade. However, Eric Odeblad, a Swedish physicist and gynecologist, used ^1H NMR to study body fluids as far back as 1957.^{1,2} Although the spectra were relatively uninformative, he advocated the establishment of a 'department of medical research with NMR.' In the early 1970s, the introduction of Fourier transform spectroscopy, together with technical advances (field strength, coil designs, pulse sequences, and computing) enabled the use of high-resolution NMR for the detection and identification of different chemical species in biological systems. In 1979, Ohsaka et al.³ reported high resolution proton NMR spectra of intact body fluids and attempted sero-diagnosis of cancer. Their spectra consisted of sharp resonances from low-molecular-mass metabolites superimposed on broad resonances from macromolecules, with an elevated lactate signal as a criterion for diagnosis of cancer. This was closely followed by a study of high-resolution NMR spectra of urine samples from subjects with diabetes and renal failure.⁴ Marked changes in the concentration of a number of then unidentified endogenous metabolites were observed. From these preliminary studies, it became clear that high resolution NMR could play an important role in the study of body fluids.

The first full clinical use of NMR to study body fluids was in a study of metabolic disorders by Bock and coworkers.^{5,6} Elevated concentrations of D-lactate were detected in serum samples from human subjects following jejunoileal bypass. Full characterizations of different body fluids by high-resolution NMR and application to a wider range of biochemical and clinical problems came soon afterwards. Since then, the study of body fluids by high resolution NMR spectroscopy has become an increasingly expanding area of research.

1.2 The Range of Body Fluids

The biochemical composition of body fluids is known to reflect the metabolic status of the donor. Thus, detailed knowledge of the composition of body fluids is likely to provide good insight into the biochemical and clinical status of the donor. This has led workers to apply a variety of techniques to obtain metabolic profiles of body fluids. However, most of the

standard techniques require extensive sample preparation together with careful selection of analytical conditions. This can clearly restrict the number of compounds that can be studied at a given time. Moreover, a number of fluids contain a range of molecules with diverse chemical and molecular masses, including amino acids, proteins and lipoproteins, all or some of which can be affected in disease. The nonselective nature of NMR spectroscopy makes it an ideal technique for obtaining metabolic profiles of all available body fluids. Furthermore, NMR spectroscopy can give useful insights into molecular interactions within intact fluids which are not readily available by standard biochemical techniques. Thus, NMR spectroscopy, although relatively insensitive, has been successfully applied to the detection and quantitation of a variety of molecules in intact body fluids, including blood, blood plasma, serum, urine, cerebrospinal fluid (CSF), bile, synovial fluid, seminal fluid, milk, saliva and sweat (Table 1).⁷⁻⁶⁰ Representative ^1H NMR spectra of some body fluids are shown in Figure 1.

The physicochemical composition of different body fluids varies widely. Fluids such as plasma, bile, CSF, seminal fluid and synovial fluid contain both macromolecules, low-molecular-mass compounds and inorganic ions. These compounds range from complex lipoproteins and glycoproteins to relatively simple organic acids, amino acids and metal ions. Less complicated body fluids include urine, aqueous humor, saliva, and sweat, which contain relatively low levels of macromolecules, but often a very large number of different low-molecular-mass metabolites (Table 1). The ^1H NMR chemical shifts of some common metabolites are listed in Table 2. NMR spectroscopy can provide qualitative and quantitative information about most of these body fluids components, often in just a few minutes, as well as information about molecular structures, molecular interactions and dynamics.

1.3 Sample Preparation and NMR Data Acquisition

NMR spectra can be readily obtained from intact body fluids, requiring little or no sample preparation. Samples (usually about 500 μL) can be examined untreated in the spectrometer, except that normally a small amount of a deuterated solution is added to provide a field/frequency lock (e.g. 5–10% v/v D_2O or saline). This can be added directly to the sample, or placed in a capillary tube, thus avoiding dilution of sample. Particular care should be taken with the storage of samples. For example, contaminating bacteria can introduce exogenous substances, and freezing and thawing can cause chemical changes such as precipitation and protein denaturation. Buffering can be a problem. For example, the main natural buffer in blood plasma is bicarbonate/ CO_2 and the pH of samples can rise rapidly after storage due to the volatility of CO_2 . This can be counteracted by adding sodium bicarbonate (25 mM) or a small amount of another buffer (e.g. phosphate).

Reasonably resolved ^1H NMR spectra of body fluids can be obtained on commercially available high-frequency spectrometers (>400 MHz). Higher frequency NMR spectrometers (600 and 750 MHz) give increased resolution and relative sensitivity,²¹ and improve the detection and identification of body fluid components; however, these instruments are relatively expensive.

Table 1 Endogenous Metabolites detected in Body Fluids by High-Resolution ^1H NMR Spectroscopy^a**Amniotic fluid**

Acetate, α -alanine, D-3-hydroxybutyrate, citrate, creatine, creatinine, formate, glucose, glutamate, glycerophosphorylcholine, isoleucine, lactate, lecithin, leucine, lipids, lysine, methionine, ornithine, 2-oxoisovalerate, phospholipids, proline, sphingomyelin, threonine, tyrosine, valine^{55–57}

Aqueous humor

Acetate, alanine, ascorbate, citrate, creatine, formate, glucose, glutamine/glutamate, histidine, lactate, phenylalanine, threonine, tyrosine, valine^{44,45}

Bile

Acetate, acetone, acetoacetate, α -alanine, cholesterol, cholesterol esters, choline, citrate, creatine, creatinine, ethanol, ergothionine, formate, glucose, glutamate, glutamine, glycine, glycocholic acid, D-3-hydroxybutyrate, isoleucine, lactate, propionate, phosphatidylcholine, taurine, taurocholic acid, urea, valine^{39,40}

Blood plasma and serum

Acetate, acetone, acetoacetate, acetylcarnitine, *N*-acetyl sugars, *N*-acetyl glycoproteins, acylglycerols, alanine, aspartate, betaine, carnitine, cholesterol, cholesterol esters, choline, citrate, creatine, creatinine, dimethylamine, dimethylglycine, ethanol, ergothionine, formate, glucose, glutamate, glutamine, glycine, glycerol, histidine, D-3-hydroxybutyrate, *p*-hydroxyphenyllactate, isoleucine, lactate, leucine, lysine, lipoproteins (high density, low density, very low density), 1-methylhistidine, 3-methylhistidine, myoinositol, phenylalanine, phosphatidylcholine, pyruvate, succinate, threonine, trimethylamine *N*-oxide, tyrosine, urea, valine

Cerebrospinal fluid

Acetate, acetone, acetoacetate, α -alanine, aspartate, arginine, choline, citrate, citrulline, creatine, creatinine, dimethylamine, formate, fumarate, GABA, galactose, glucose, glutamine, glutamate, glycine, glycerol, D-3-hydroxybutyrate, histidine, indoxyl sulfate, inositol, isoleucine, lactate, leucine, lysine, mannitol, methionine, proline, pyruvate, phenylalanine, spermidine, succinate, taurine, threonine, trimethylamine *N*-oxide, tyrosine, valine.

Cystic fluid

Acetate, *N*-acetyl glycoproteins, alanine, arginine, citrate, creatine, dimethylamine, ethanol, formate, glucose, glutamine, histidine, isoleucine, lactate, lysine, phenylalanine, succinate, threonine, tyrosine, urea, valine⁵⁸

Follicular fluid

Acetate, *N*-acetyl sugars, *N*-acetyl glycoproteins, alanine, creatine, creatinine, ethanol, glucose, glycine, D-3-hydroxybutyrate, lactate, valine⁴⁹

Gastric fluid

Histidine, tyrosine, phenylalanine⁵⁰

Milk

Acetate, alanine, citrate, creatine, formate, glucose, lactose, lactate, lipids, taurine⁵¹

Saliva^{41,42}**Seminal fluid**

Acetate, alanine, arginine, aspartate, asparagine, D-3-hydroxybutyrate, choline, citrate, creatine, cystine, dimethylamine, formate, fumarate, fructose, glucose, glutamate, glutamine, glycine, glycerophosphorylcholine, histidine, inositol, isoleucine, lactate, leucine, lysine, methionine, phenylalanine, phosphorylcholine, proline, pyruvate, spermidine, spermine, taurine, threonine, trimethylamine *N*-oxide, tryptophan, tyrosine, uridine, valine^{46–48}

Sweat

Acetate, alanine, D-3-hydroxybutyrate, citrate, glutamate, glutamine, glycine, histidine, lactate, tyrosine, valine⁴³

Synovial fluid

Acetate, acetone, acetoacetate, *N*-acetyl sugars, *N*-acetyl glycoproteins, α -alanine, cholesterol, cholesterol esters, choline, citrate, creatine, creatinine, ethanol, formate, glucose, glutamine, glycine, histidine, D-3-hydroxybutyrate, lactate, lipoproteins, phenylalanine, threonine, tyrosine, valine^{43,52–54}

Urine

Acetate, acetamide, acetone, acetoacetate, acetylcarnitine, *N*-acetyl sugars, α -alanine, β -alanine, allantoin, anserine, ascorbate, betaine, butanone, carnitine, choline, citrate, creatine, creatinine, dimethylamine, dimethylglycine, ethanol, formate, glucose, glutamate, glutamine, glutarate, glycine, guanine, hippurate, histidine, hydroxybenzoate, D-3-hydroxybutyrate, 2-hydroxyisocaproate, 2-hydroxyisovalerate, 2-hydroxy-3-methylvalerate, hydroxypropionate, indoxyl sulfate, inositol, isoleucine, isovaleryl glycine, 2-oxoglutarate, lactate, leucine, lysine, methanol, methionine, methylamine, methylmalonate, *N*-acetyl glycoproteins, 2-oxoisocaproate, 2-oxoisovalerate, 2-oxo-3-methylvalerate, phenylalanine, propionate, propionylcarnitine, propionylglycine, succinate, taurine, trimethylamine, trimethylamine *N*-oxide, threonine, tyrosine, urea, valine

Vitreous fluid

Acetate, alanine, citrate, creatine, formate, glutamine/glutamate, lactate, valine⁴⁵

^aReferences given are mostly to work not described in the text.

In general, ^1H NMR spectra of body fluids with good signal-to-noise ratios can be obtained within a few minutes. The acquisition of NMR spectra of body fluids requires consideration of two major factors: T_1 and T_2 relaxation, and water suppression. Fully-relaxed ^1H NMR spectra can usually be obtained with 35° pulses and a 3-s pulse repetition time. ^{13}C NMR spectra require up to 10 s to allow full relaxation of some lipid and protein components. For some body fluids, spin echo techniques are useful for the suppression of broad resonances from macromolecules.¹² T_2 effects, which can affect the

quantitation of metabolites, must be taken into account during the analysis of these spectra.

Water suppression is crucial for ^1H NMR experiments on body fluids since the concentration of water protons is about 10^5 times that of the protons in the metabolites of interest. Although freeze-drying and redissolution in D_2O is very effective, volatile metabolites may be lost and the structures of some macromolecules may be altered by this process.²³ The most commonly used method for suppression is presaturation⁶¹ (secondary irradiation during the relaxation delay, e.g. for 1 s),

although this does not allow detection of peaks very close to the water peak. For the latter purpose the WATR method⁶² (water attenuation by T_2 relaxation) is very effective. This involves addition of a water relaxation agent (e.g. NH_4Cl) and use of the CPMG spin echo sequence with a short refocusing time so that normal multiplets without phase modulation are obtained. Details of other methods can be found elsewhere in this volume. Many suppression methods lead to distortions in peak intensities and this has to be checked if quantitative information is required. It seems likely that increasing use will be made of field gradient water suppression methods in future. Other advances are likely to include the use of microprobes requiring only about 50 μL of sample, and, at the other extreme, larger sample volumes (e.g. 4 mL in a 10 mM tube) which provide high sensitivity.

2 DIAGNOSIS AND MOLECULAR INTERACTIONS

2.1 Organ Dysfunction

The biochemical profile of a body fluid is known to reflect the metabolic status of the donor. Thus, the unique exploratory nature of NMR makes it an ideal technique for the study of body fluids from subjects with organ dysfunction. This is clearly reflected in published work which includes analysis of plasma, CSF, urine and bile from subjects suffering from liver failure,^{8,39} brain tumors,²⁴ organ transplant,²¹ and renal failure.¹⁶ For example, increased concentrations of aromatic amino acids have been observed in NMR spectra of plasma of subjects with hepatic failure,^{8,39} while variations in plasma *N*-acetyl resonances correlate with acute heart rejection.¹⁴

An important area of clinical and biochemical research has been the application of high-resolution NMR spectroscopy to the study of the biochemical abnormalities associated with chronic renal failure (CRF).^{16,21} Renal damage in both animals and humans has been shown to give rise to altered profiles for low-molecular-mass metabolites of urine and plasma, which in turn is reflected in the NMR spectral fingerprint. Bell et al.¹⁶ used ^1H NMR to show that plasma and urine from subjects' CRF had increased levels of creatinine, trimethylamine oxide (TMAO) and dimethylamine. These amines had not been previously detected in body fluids from human subjects and have since become valuable markers to monitor renal transplant function. Since then several novel markers of renal dysfunction have been identified by NMR,²¹ including TMAO, dimethylamine (DMA), dimethylglycine (DMG), 1-methylhistidine and 3-methylhistidine, thus giving a new perspective to the uremic condition and the effects of hemodialysis on body fluid composition. The contribution of NMR spectroscopy of body fluids to renal transplantation has been clearly highlighted by Foxall

Valine	0.98 (d), 2.26 (m), 3.55 (d)

^aNote that the shifts may vary with pH, ionic strength and temperature.

et al.²¹ (Figure 2). They have shown that significantly higher concentrations of TMAO can be observed for urine collected from patients during episodes of graft dysfunction compared with urine from patients with good graft function or from healthy control subjects. Furthermore, they suggest that graft dysfunction is associated with damage to the renal medulla, which causes the release of TMAO into the urine, thus providing a novel urinary marker for posttransplant graft dysfunction.

2.2 Metabolic Disorders

The nonselective nature of NMR spectroscopy makes it the method of choice for the study of intact body fluids, especially for the study of congenital errors of metabolism. NMR spectroscopy allows rapid and accurate diagnosis of different metabolic disorders, with the added advantage that novel metabolites related to a given disease can be detected, thus improving diagnosis and possible therapy. A large number of inherited metabolic disorders have been successfully studied by NMR spectroscopy, including maple syrup urine disease, isovaleric aciduria, dicarboxylic aciduria, and tyrosinemia.^{31,33,38,43} A few examples are used here to illustrate the potential of NMR spectroscopy in this area of research.

By simple NMR urinalysis, Iles and Chalmers³¹ were able to monitor the progression of the disease, the fate of the therapeutic compounds and the restoration of metabolic balance in a girl with a defect in propionic acid metabolism, methylmalonic aciduria. The ^1H NMR spectrum of urine from this patient is shown in Figure 3. The subject was given intravenous carnitine in an attempt to resolve a severe episode of acute metabolic decompensation.

Carnitine is known to reduce the propionate pool by combining with propionyl-CoA to form propionylcarnitine. The latter is excreted in the urine. Spectra taken during this acute episode showed: (1) the range of metabolites associated with the disorder, including methylmalonate and creatine; (2) the metabolic fate of the therapeutic intervention in the form of unchanged carnitine and propionylcarnitine; and (3) the appearance of acetylcarnitine, signifying restoration of acetyl-CoA metabolism on lowering the level of intracellular propionyl-CoA. The appearance of acetylcarnitine coincided with clinical

Uremic

Cr, creatine; Cn, creatinine; Cho, choline; TMAO, trimethylamine N -oxide; Ins, myoinositol; Gly, glycine; Thr, threonine; Val, valine; Gol, glycerol; Ala, alanine; Tyr, tyrosine; His, histidine; Phe, phenylalanine; Lac, lactate; 3-OHB, D-3-hydroxybutyrate. (Adapted from P. J. D. Foxall, M. Spraul, R. D. Farrant, L. C. Lindon, G. H. Neild, and J. K. Nicholson, *J. Pharmacol. Biomed. Anal.*, 1993, **11**, 267)

improvement of the patient. Since the acquisition of an NMR spectrum from urine takes less than 3 min (at 500 MHz), this type of research opens up the possibility of 'real-time' therapeutic monitoring.

Although, ^1H NMR spectroscopy is the preferred method for the study of congenital errors of metabolism, dynamic metabolic studies have been carried out via ^{13}C NMR spectroscopic studies of body fluids following the infusion of ^{13}C -enriched metabolites. Tanaka et al.⁶³ used ^{13}C NMR urinalysis to monitor the fate of valine in methylmalonic aciduria. Following intravenous injection of DL-[1- ^{13}C]- and DL-[1,2- ^{13}C]valine to a boy with cobalamin-responsive methylmalonic aciduria, ^{13}C NMR spectra of urine showed that propionate was an obligatory intermediate from valine to methylmalonyl-CoA. It was previously thought that propionate was bypassed via methylmalonic semialdehyde. A similar approach was taken by Lapidot¹³ in studies of glycogen storage and inherited fructose intolerance diseases in children. By means of a combination of ^{13}C NMR spectroscopy, and isotopomer analysis with gas chromatography-mass spectrometry, following nasogastrically infused [U- ^{13}C]glucose, they were able to gain an insight into the biochemical altera-

tions in specific metabolic pathways which accompany these diseases.

2.3 Proteins and Lipoproteins in Intact Fluids

Blood plasma and serum are heterogeneous fluids containing lipoprotein particles (about 5–1200 nm in diameter), macromolecules (proteins), small molecules and ions. Any of the normal anticoagulants can be used for preparing plasma for NMR studies, e.g. EDTA and lithium heparin. The former is often preferred for lipoprotein work and gives rise to peaks for CaEDTA (NCH_2 singlet at 2.57 ppm) and MgEDTA (2.76 ppm) in spectra. No interfering peaks are usually seen for heparin.

Simplification of ^1H NMR spectra of plasma (which are similar to those of serum) can be achieved by the use of spin echo methods to filter out the broadest resonances.^{7,9,12} No resonances remain in the aromatic region with t values greater than about 30 ms. Spin echo spectra can be used to study small molecules such as valine, acetate, alanine, lactate, glucose, and the ketone bodies acetone, acetoacetate and D-3-hydroxybutyrate in cases of insulin-dependent diabetes or fasting,^{7,9} as well

Figure 3 The 500 MHz ^1H NMR spectrum of urine sample from a subject with a defect in propionic acid metabolism. PC, propionylcarnitine; Me, methylmalonic acid; AC, acetylacarnitine; C, carnitine; Cr, creatine; Cr, creatinine; Gly, glycine. (Adapted from figure supplied by R. A. Iles)

as mobile segments of lipoproteins and acute-phase glycoproteins.

2.3.1 Proteins

Broad resonances at 2.04 and 2.08 ppm in ^1H NMR spectra of blood plasma have been assigned to the *N*-acetyl groups of *N*-acetylglucosamine and *N*-acetylneuramic acid residues of the glycan chains of 'acute-phase' glycoproteins such as α_1 -acid glycoprotein.⁶⁴ These resonances have been used to monitor increases in maternal levels of these proteins (which are two-fold) compared with the matched neonatal cord plasma,⁶⁵ and the progress of heart transplant rejection.⁶⁶

The application of resolution enhancement to high-field ^1H NMR spectra of blood plasma enables the detection of specific resonances for the major plasma protein albumin (66 kDa), including those for the N-terminal amino acids Asp1-Ala2-His3.²⁰ The ^1H NMR resonances of H₁₅₃ of albumin can be used to monitor the state of Cys34 of albumin in blood plasma, and the formation of disulfides with, for example, the alcohol-aversive drug disulfiram and adducts with gold antiarthritic drugs.⁶⁷

2.3.2 Lipoproteins

There is particular interest in the determination of lipoprotein concentrations in blood plasma on account of their association with coronary heart disease, hyperlipidemias, and possibly cancer and other diseases.

Broad resonances from the CH_2 and CH_3 groups of the fatty acid constituents of, for example, triacylglycerols, phospholipids and cholesterol esters in lipoproteins occur near 1.2 and 0.9 ppm, respectively. Comparisons of the ^1H NMR spectra of the individual isolated lipoproteins¹⁰ enabled specific assignments to be made for each of the four major classes of lipoprotein (Figure 4), and suggested that ^1H NMR spectroscopy would allow a rapid determination of lipoproteins in intact plasma or serum. Both the CH_2 and CH_3 peaks shift slightly to high field as the density of the particle increases. The origin of the shifts is not yet clear, but may be related to susceptibility effects, protein interactions [greatest for high-density lipoprotein (HDL)], and the different types of lipid involved (higher proportion of phospholipids in denser particles). Lipoprotein classes can also be distinguished by their differing relaxation properties; in Hahn spin echo spectra, the NMe_3^+ peak from choline headgroups of phospholipids in low-density lipoprotein (LDL) and HDL decays more rapidly with increasing refocusing time for LDL than for HDL, and the CH_2 of LDL but not HDL contributes to the methyl and methylene region with longer TE values (60 ms).

Two approaches have subsequently been used to simulate the CH_2 and CH_3 regions of spectra of blood plasma and determine lipoprotein concentrations. In the first,¹⁵ mean experimental 250 MHz spectra of isolated lipoprotein fractions have been used to construct plasma lipid CH_3 resonances using a linear least-squares fitting routine. Since this region of ^1H spectra of plasma from different donors is relatively similar for different donors, this procedure is reasonably successful. It has been refined⁶⁸ by including subspecies distributions within each lipoprotein class [very-low-density lipoprotein (VLDL), LDL, HDL], effectively broadening the peaks for each [Figure 5(a)]. For LDL the subspecies distributions derived from NMR correlated well with those from gradient-gel electrophoresis.

Figure 4 Assignments for the CH_3 and CH_2 ^1H NMR resonances of lipoproteins in Hahn spin echo spectra (TE = 60 ms). Chyl, chylomicrons; VLDL, very-low-density lipoproteins; LDL, low-density lipoproteins; HDL, high-density lipoproteins. The peak at 3.25 ppm in the insert is from the choline headgroup of HDL phospholipids. (Adapted from J. D. Bell, P. J. Sadler, P. J. Macleod, P. R. Turner, and A. LaVigne, *FEBS Lett.*, 1987, **219**, 239)

These NMR measurements were carried out at 45 °C so as to avoid the problems caused by the increasing linewidth with temperature of peaks for LDL (the midpoint of the phase transition is at about 32 °C).

In a second approach the spectra of the CH_2 peaks of 400 MHz spectra of isolated individual lipoproteins at 30 °C were simulated by resolvable Lorentzian component lines:¹⁷ two for VLDL, three for LDL, and two for HDL [Figure 5(b)]. NMR determinations of the relative amounts of each lipoprotein fraction in the plasma of normolipidemic and hyperlipidemic subjects using these model resonances gave good agreements with biochemical determinations.

Further refinements of these procedures can be envisaged involving inclusion of all the lipid peaks in the spectrum in the analysis, and consideration of modified lineshapes for lipoprotein particles with a high content of polyunsaturated fatty acids, e.g. for subjects on high fish oil content diets.⁶⁹ Halogenated anesthetics can mobilize lipids within lipoprotein particles⁷⁰ and there may also be lipophilic drugs which have such effects. ^{13}C and ^{31}P NMR analyses may be useful complements to ^1H work.

Figure 5 (a) The methyl ^1H NMR resonances of lipoproteins at 250 MHz, 45°C. VLDL, very-low-density, lipoproteins; L_L and L_S , large and small LDL; H_L and H_S , large and small HDL. (Adapted from J. D. Otvos, E. J. Jeyarajah, D. W. Bennett, and R. M. Krauss, *Clin. Chem.*, 1992, **38**, 1632). (b) Experimental and calculated lipoprotein ^1H NMR CH_2 peaks for VLDL, LDL and HDL, and intact human blood plasma. (Adapted from M. Ala-Korpela, Y. Hiltunen, and J. Jokisaari, *NMR Biomed.*, 1993, **6**, 225)

Figure 6 (a) Lactate binding in blood plasma. 500 MHz single pulse (bottom) and Hahn spin echo ($\text{TE} = 60$ ms) ^1H NMR spectra (top) of human blood plasma before and after addition of ammonium chloride. The increase in intensity of the lactate methyl resonance with ammonium chloride concentration is plotted in the inset. (Adapted from J. D. Bell, J. C. C. Brown, G. Kubal, and P. J. Sadler, *FEBS Lett.*, 1988, **235**, 81.) (b) Ni^{2+} binding to the N-terminus of albumin in human blood plasma. Resolution-enhanced (combined exponential and sine-bell functions) 500 MHz ^1H NMR spectra of the aromatic region of human blood plasma before (lower) and after (upper) addition of Ni^{2+} (0.5 equivalents with respect to albumin). Alb-His3 refers to the third residue in albumin. Ni^{2+} binds to the N-terminal Asp1-Ala2-His3 residues forming a square-planar, diamagnetic complex. (Adapted from S. U. Patel, P. J. Sadler, A. Tucker, and J. H. Viles, *J. Am. Chem. Soc.*, 1993, **115**, 9285)

A rapid method for separation of lipoproteins from plasma for NMR work is that described by Hoffman et al.,⁷¹ which involves the use of 1.5 mL of a gel such as Sepharose 6B in a disposable Pasteur pipet eluted with a deuterated salt solution.

It should be noted that, despite initial claims,⁷² there is no useful relationship between the linewidths of lipoprotein CH₂ and CH₃ ¹H NMR resonances and cancer diagnosis, although they are reported to be of value for monitoring heart transplant rejection.⁷³ The use of 'star plots' (graphical display of peak height ratios) has been advocated for the detection of metabolic modifications brought about by cancer evolution or therapy.⁷⁴

Kaartinen et al. have demonstrated that clinically relevant lipid classifications can be obtained from self-organizing map analysis of ¹H NMR spectra of blood plasma.⁷⁵ It has been suggested that the pattern of resonances at 1.17, 1.18 and 1.20 ppm can be used to measure other levels of oxidized low-density lipoprotein in human serum with possible application to cardiovascular risk factor profiles.⁷⁶ The advantages of using high frequency ¹H (800 MHz) and ¹³C NMR spectroscopy for improving the resolution of lipid peaks are apparent.⁷⁷

2.3.3 Molecular Interactions and Binding

Considerable caution has to be exercised in the interpretation of the intensities of peaks in spin echo spectra of plasma. The long *T*₁ values of some small molecules have to be taken into account when pulsing conditions for quantitation experiments are chosen (e.g. acetate 3.6 s, formate 6.6 s, glycine 2.4 s, valine 1.1 s; serum, pH 7, 400 MHz, 22 °C, 0.8 M NH₄Cl

added).⁷⁸ To allow the rapid quantitation of small molecules in the plasma from subjects with chronic renal failure (CRF), Grasdalen et al.⁷⁹ applied correction factors to compensate for the effects of relaxation and water irradiation on peak intensities.

Reliable quantitation can be obtained for alanine and valine with standard additions, but lactate and some other carboxylic acids bind to plasma macromolecules. Lactate has been shown to bind to both transferrin¹¹ and albumin⁸⁰ in slow exchange on the NMR timescale. It can be displaced from binding by addition of NH₄Cl [Figure 6(a)],¹¹ the antihypertensive drug Captopril,⁸⁰ and the anticonvulsant agent [Cu₂(DIPS)₄] (DIPS is 3,5-diisopropylsalicylate).¹⁸ Intriguingly, there appears to be less lactate binding in plasma from subjects with CRF than in normal plasma.¹⁶ A noncovalent interaction between Captopril and albumin has been detected in blood plasma and the *cis* isomer undergoes faster exchange between free and bound forms than does the *trans* isomer.⁸⁰ Binding of Cu²⁺ to formate and histidine in urine has been studied by NMR, and the time-course of the reaction between copper ethylenediaminetetraacetate (CuEDTA) and blood plasma has been monitored.¹⁸ Even at relatively low levels of Al³⁺ ions (50 μM), binding to citrate can be detected, which is reversed by the therapeutic chelating agent desferrioxamine.¹⁹ The binding of Ni²⁺ to the N-terminal site of albumin (the antigenic determinant in cases of Ni²⁺ allergy) can be studied directly in plasma²⁰ [Figure 6(b)]. These kinds of experiment offer promise in the metallo-drugs field, since ligand exchange and redox reactions in biological media are common, and alternative methods which involve the separation of the components can lead to changes in metal speciation.

Figure 7 The 500 MHz ¹H NMR spectrum of human urine 6 h after a therapeutic 1 g (6.6 mmol) dose of the analgesic drug paracetamol. As well as natural metabolites (Cn, creatinine; Cit, citrate; D, dihydroxyacetone; Fm, formate; Gly, glycine; Hip, hippurate), peaks for the drug (1) and all its major metabolites (2–5) are seen. (Adapted from J. D. Bell, J. C. C. Brown, and P. J. Sadler, *Chem. Br.*, 1988, **24**, 1021)

Although a useful reference for chemical shifts and concentrations in body fluids with low levels of macromolecules, trimethylsilylpropionate (TSP) is often undetectable at <2.5 mM in ^1H NMR spectra of blood plasma, due to binding.⁷⁸ Similarly, resonances for phenylalanine and tyrosine are suppressed in spin echo spectra of blood plasma at normal pH compared with highly acidic pH values (<2.5). The interaction of glutamine with other components of CSF is markedly changed after freeze drying and redissolving the sample, only then are its ^1H NMR resonances visible.²³

3 DRUG METABOLISM AND TOXICOLOGY

NMR spectroscopy is finding increasing uses in the study of drug metabolism and toxicology.⁵⁹ Conventional techniques require the use of radioactive labeling and extensive use of separation techniques, e.g. high-performance liquid chromatography (HPLC). Moreover, valuable information can be lost using conventional techniques since exogenous and endogenous metabolites can go undetected. NMR spectroscopy, however, allows observation of all metabolites in one experiment^{27–30} (Figure 7), although it suffers from inherently low sensitivity and 'chemical noise'. Chemical noise refers to the many low-intensity resonances found in body fluids that may mask the resonances under study. In part these problems can be overcome by concentrating the samples and by the use of multidimensional/multinuclear NMR. A more recent and powerful approach is the separation of metabolites by solid-phase extraction/chromatography in conjunction with NMR (SPEC-NMR) or HPLC coupled with high-field NMR.

NMR spectroscopy has been successfully applied to the study of a variety of xenobiotics including, acetaminophen, 5-fluorouridine, ifosfamide, ibuprofen, penicillamine, flucloxacillin, ampicillin, hydrazine, *N*-methylformamide, and carboplatin.^{59,81} ^1H and ^{19}F are usually the nuclei of choice in NMR studies of xenobiotics, although work using ^{31}P , ^2H and ^{15}N has been published. The advantages of ^1H NMR are clearly based on its high sensitivity and the fact that protons are ubiquitous to most drugs. However, ^1H NMR spectra often suffer from severe overlap of signals from exogenous and endogenous metabolites. On the other hand, ^{19}F NMR is particularly good for these studies in that it has high sensitivity, 100% natural abundance and no interference from naturally-occurring fluorinated compounds, and therefore no chemical noise. A good illustration of the use of NMR spectroscopy in drug metabolism is that of 5-fluorouracil (5FU).³² The complete urinary excretion profile of cancer patients on a drug course of 5FU was followed by ^{19}F NMR spectroscopy with and without methotrexate pretreatment. The parent drug (5FU) and four of its metabolites were detected in the urine, including F^- which is produced as a degradation product. The major metabolite found in these studies was α -fluoro- β -alanine.

A new area of research has been the development of NMR of body fluids in analytical toxicology. Nicholson and co-workers^{34–36} have used NMR for the rapid multicomponent analysis of body fluids following xenobiotic insults. The effects of known nephrotoxins on the NMR profiles of rat urine were investigated. The nephrotoxins consisted of sodium chromate (pars convoluta of proximal tubule), cisplatin, hexachlorobutadiene, mercury(II) chloride (pars recta of the proximal tubule),

propylene imine, and 2-bromoethanamine (renal papilla). These compounds induced damage in specific regions of the rat kidney. Urinalysis by ^1H NMR spectroscopy showed clear biochemical fingerprints for site-specific nephrotoxic states (Figure 8). Aminoaciduria, glycosuria, and lactic aciduria were characteristic of exposure to all proximal tubular toxins (except for cisplatin), whereas papillary insult resulted in early elevations in urinary TMAO and DMA. TMAO and DMA were suggested as markers of site-specific renal papillary injury in the rat.

Toxicological studies in humans have been more limited. However, a number of cases have arisen from accidental or self-inflicted poisoning episodes, e.g. paracetamol (acetaminophen) overdose and accidental skin adsorption of phenol.³⁵ Although these studies are partly hampered by the lack of control of body fluids, useful clinical and biochemical information

Figure 8 Effects of administration of various nephrotoxins on the ^1H NMR spectra (400 MHz) of rat urine. (a) Control; (b) 24–48 h after dosing with 20 mg kg^{-1} sodium chromate (pars convoluta proximal tubular toxin); (c) 24–48 h after dosing with 50 mg kg^{-1} *p*-aminophenol (pars recta proximal tubular toxin); (d) 24–48 h after dosing with 20 ml kg^{-1} propylene imine (produces renal medullary necrosis). DMA, dimethylamine; 2-OG, 2-oxyglutarate; hipp, hippurate; cn, creatine; gln, glutamine; lys, lysine; TMAO, trimethylamine *N*-oxide. (Adapted from K. P. R. Gartland, F. W. Bonner, and J. K. Nicholson, *Mol. Pharmacol.*, 1989, **35**, 242)

has been obtained. These results clearly demonstrate the strength of the NMR technique as applied to toxicological studies.

Proton NMR spectra of body fluids consist in many cases of a very large number (>100) of resonances, giving rise to a wealth of, as yet complex, information. Spectral quantitation and interpretation can thus become tedious and time-consuming. Furthermore, metabolic alterations in the body can lead to subtle, yet consistent changes in the composition profiles of some body fluids. In many cases standard quantitative and statistical analysis of the spectral data are not robust enough to detect some of these changes. Alternative computer-based pattern-recognition methods^{36,59} have been applied to analyses of NMR spectra of body fluids. Preliminary results suggest that pattern-recognition methods applied to NMR data may be powerful for the characterization of metabolic abnormalities associated with diseased states and toxicological events.

1 INTRODUCTION: THE IMPORTANCE OF CATION GRADIENTS FOR CELL FUNCTION

Intracellular cations play critical roles in cell division and maintaining normal cell function in both prokaryotic and eukaryotic cells, and cells actively regulate their intracellular cation levels. Large concentration gradients of the monovalent cations Na^+ , K^+ , and H^+ , and the divalent cations Ca^{2+} and Mg^{2+} , exist across the plasma membrane. The quintessential example of the role of cation movements in normal cell function is the control of excitation-contraction coupling in striated muscle. During a twitch in skeletal muscle and during each cardiac cycle, Na^+ , Ca^{2+} , H^+ , and K^+ (as well as other charged species) move across the plasma membrane to initiate a sequence of events leading to contraction: Na^+ and Ca^{2+} move from the interstitium to the intracellular space while K^+ and H^+ move out of the cell. Muscle relaxation occurs when the concentrations of these critical cations (most importantly Ca^{2+}) return to baseline. Recovery of resting cell intracellular cation concentrations requires energy. Furthermore, maintenance of intracellular Na^+ and Ca^{2+} levels (Na_i and Ca_i), which in the quiescent cell are below their electrochemical equilibrium values, requires energy. The source of energy for these cation movements is the hydrolysis of ATP, either directly via membrane proteins that stoichiometrically couple ATP hydrolysis and ion translocation, or indirectly through the Na^+ gradient.

Intracellular concentrations of Na^+ , K^+ , H^+ , and Ca^{2+} are determined by the integrated action of these membrane proteins: ion pumps, exchangers, and channels. Membrane proteins from organelles within the cell, namely the endoplasmic reticulum and mitochondria, are also important in the regulation of cation concentrations. A diagram summarizing

the major components of this network is shown in Figure 1. Cation NMR has been used to examine the relative contributions of these specific components to net ion movements and how this may change in pathological states. The major advantage of using NMR to measure cation contents is that repetitive nondestructive measurements can be made for intact functioning tissue, usually over long periods of time. Moreover, some of these techniques allow simultaneous measurement of extra- and intracellular ion content, thereby permitting quantitative assessment of net ion movement.

Figure 1 Diagrammatic representation of the plasma membrane of a muscle cell (sarcolemma) showing the primary pathways of Na^+ , K^+ , and Ca^{2+} movement: the ATP-dependent Na^+ and Ca^{2+} pumps, electroneutral Na^+/H^+ exchange and electrogenic $\text{Na}^+/\text{Ca}^{2+}$ exchange, Na^+ -dependent HCO_3^- exchange, $\text{H}^+/\text{lactate}$ and $\text{Na}^+/\text{H}_2\text{PO}_4^-$ cotransport, and the voltage-dependent Na^+ , K^+ , and Ca^{2+} channels. Intracellular/extracellular concentrations for Na^+ (10/144 mM), K^+ (85–130/5 mM), Ca^{2+} (10–4/1.25 mM), and H^+ (pH 7.15/pH 7.40)

Table 1 NMR Properties of Selected Nuclides

Nucleus	Spin quantum number	Natural abundance (%)	Effective sensitivity ^a ($\times 10^{-2}$)	T_1^b (ms)	T_2^b (ms)	Resonant frequency at 8.4 T (MHz)
²³ Na	$\frac{3}{2}$	100	9.3	70	54	95.2
⁷ Li	$\frac{3}{2}$	93	29.4	25×10^3	18×10^3	139.8
³⁹ K	$\frac{3}{2}$	93	0.05	54	54	16.8
⁸⁷ Rb	$\frac{3}{2}$	28	17.7	2.5	2.5	117.7
²⁵ Mg	$\frac{5}{2}$	10	—	—	—	22.0
⁴³ Ca	$\frac{7}{2}$	0.14	—	—	—	24.2

^aRelative to hydrogen. ^bMeasured in aqueous solution.

In this chapter we first describe the MRS methods for measuring monovalent cation contents and movements in intact organs. To illustrate their power, we then describe their application to the heart made ischemic by an abrupt cessation in blood flow. Our focus is on Na⁺ because it has received the most attention experimentally.

2 METHODS FOR MEASURING CATION CONTENT AND MOVEMENTS IN VIVO

Hydrogen, Na⁺ and its biological congener Li⁺, K⁺ and its biological congener Rb⁺, Mg²⁺, and Ca²⁺ all have nuclides that are active in NMR¹ (see Table 1). The high natural abundance, relatively high concentration in biological tissues, and short values for spin–lattice relaxation times combine to make Na⁺ and K⁺ amenable to direct study in biological samples using NMR. The low natural abundance of the NMR active isotopes of Mg²⁺ and Ca²⁺ precludes direct NMR observation. Because Li⁺ and Rb⁺ are biological congeners of Na⁺ and K⁺, respectively, they are also useful nuclides for the study of cation movements in biological samples. Estimates of intracellular H⁺, Mg²⁺, and Ca²⁺ contents by MRS are made using indirect techniques and are not discussed here.

2.1 MRS of ²³Na and ³⁹K

Because of its inherent NMR sensitivity, high natural abundance, high concentration in biological samples, and short T_1 values, ²³Na is the second (next to ¹H) most NMR-sensitive nucleus found in biological tissues (Table 1). The first ²³Na NMR spectrum of a biological sample was obtained in 1956; the first ²³Na image of tissue was obtained in 1981 for perfused heart.¹ Although it is the cation present in highest concentration in the intracellular space, low frequency and hence low sensitivity of the ³⁹K nuclide combine to make its detection by NMR difficult. The first ³⁹K NMR signal from tissue was made in 1970;² the first in perfused heart in 1985.³ The ²³Na and ³⁹K nuclei do not exhibit any significant chemical shifts in aqueous solutions. Cations, such as Na⁺ or K⁺, do not bond covalently but bind electrostatically at suitable anionic sites. Hence, the electronic environment about the nucleus is relatively constant. While such binding may give rise to a

small chemical shift, it is more likely to result in line broadening or intensity changes. For the most part, Na⁺ and K⁺ will remain as hydrated cations in aqueous solution. The electron density around the nucleus does not change, and there are no differences in chemical shift. Therefore, the resonance frequencies of intracellular and extracellular cations are indistinguishable.

Two general approaches have been attempted to discriminate between the resonances of intracellular and extracellular cations. The first approach attempts to use characteristic intrinsic properties of the cation nuclei. The ²³Na (and presumably all spin- $\frac{3}{2}$ nuclides) resonance of cells and tissues is predominantly homogeneous biexponential: narrow central resonance ($\frac{1}{2} \rightarrow \frac{1}{2}$ transition) superimposed on two satellite coherences ($\frac{3}{2} \rightarrow \frac{1}{2}$) and ($-\frac{1}{2} \rightarrow -\frac{3}{2}$).⁴ Since spin $\frac{3}{2}$ nuclei have four nuclear spin states and three single-quantum NMR transitions, more than one relaxation rate exists in biological samples. Several investigators have explored the possibility that multiple quantum NMR can detect differences in relaxation rates of nuclei located in the intra- versus extracellular spaces in biological samples.^{5–7} It is clear that more than one rate constant is required to describe observed relaxation of cations present in both the intra- and extracellular spaces. Consequently, quantitative analysis of Na⁺ (or K⁺) signals distributed in either intra- or extracellular spaces using a multiple quantum approach is technically problematic. However, in practical terms, changes in multiple quantum signals may reflect primarily changes in either the intra- or extracellular Na⁺ (or K⁺), allowing for good estimates to be made.

The second approach to discriminate between the intra- and extracellular Na⁺, signals is to use hyperfine frequency-shift reagents. In the early 1980s, two groups independently developed shift reagents for cations.^{8,9} Dysprosium (III) tripolyphosphate (Dy(PPP)₂⁷⁻)⁹ and triethylenetetramine-hexaacetate-dysprosium (III) (DyTTHA³⁻)¹⁰ were widely employed. More recently, another shift reagent, the thulium (III) complex of 1,4,7,10-tetraazacyclo-dodecane-*N,N',N'',N'''*-tetra(methylene-phosphonate) (TmDOTP⁵⁻) was introduced.¹¹ The putative structures of these three shift reagents are shown in Figure 2. These shift reagents have been successfully used to discriminate between ²³Na and ³⁹K NMR signals arising from the intra- and extracellular spaces in a wide variety of biological samples, ranging from single cells such as yeast^{12,13} and red blood cells,¹⁴ to isolated perfused tissues such as heart³ and to organs within the intact animal^{15–17}.

Figure 2 Putative structures for the three shift reagents currently in use to discriminate intra- and extracellular Na^+ , K^+ , and Li^+ NMR signals in biological systems. 2.1.1 Properties of Frequency Shift Reagents

Aqueous shift reagents enable the spectroscopist to vary the resonance frequency of nuclei such as ^{23}Na , ^{39}K , ^{25}Mg , and ^{43}Ca . All shift reagents for cations consist of a paramagnetic ion, typically one of the lanthanides such as dysprosium, chelated to an anionic ligand (or ligands). The net negative charge on the chelated lanthanide complex is necessary for interaction between the cation and the shift reagent. The anionic character of shift reagents also minimizes binding to biological macromolecules and to membranes, essentially precluding their entry into the cell.

In general, the change of the observed chemical shift of a cation induced by the presence of a paramagnetic compound includes a diamagnetic contribution owing to a complex formation, contact hyperfine shift, and dipolar hyperfine (pseudocontact) shift. In the case of shift reagents for cations, the cation does not bond directly to the lanthanide; consequently, the contact hyperfine shift does not contribute. The complex formation shift term is negligible. As a result, the shift induced by a shift reagent is primarily from the dipolar hyperfine shift.

A magnetic dipolar interaction between the paramagnetic metal ion of the shift reagent and the cation nucleus shifts the resonance frequency of the observed nucleus. The nature of the dipolar interaction requires a specific binding site (or sites) for the cation on the complex relatively close to the paramagnetic center. The binding of the cation is relatively weak or labile; as a result, all the cationic nuclei in the sample interact briefly with the site and the lifetime of the bound cation is very short. If the average lifetime of the cation is much less than the

inverse of the frequency difference between the bound and the free cation, only one resonance frequency will be observed (rapid exchange on the NMR time scale).

The direction of the observed shift, either upfield (decreasing frequency) or downfield (increasing frequency), is a characteristic of the particular shift reagent complex and the lanthanide ion. For example, substituting the lanthanide thulium for dysprosium with the same chelate results in a reversal of the direction of the observed shift. Different chelates of the same lanthanide ion can cause shifts in opposite directions. The magnitude of the observed shift for each particular shift reagent depends on the ratio of shift reagent to cation, adding more shift reagent at constant cation concentration results in a greater shift. The magnitude also depends on the total cation content. For example, adding more K^+ to a shift reagent solution decreases the observed shift in a ^{23}Na NMR spectrum. Divalent ions, such as Ca^{2+} , typically bind more strongly to the shift reagent and are, therefore, more effective at reducing the observed shift.

The dipolar shift described above is usually the dominant mechanism by which cation resonance shifts are induced by shift reagents. However, in any NMR sample the chemical shift can be affected by bulk magnetic susceptibility (BMS). The susceptibility shifts are the result of shielding effects produced by the surrounding medium, not the local electrons. Paramagnetic compounds produce large magnetic susceptibility effects. This type of paramagnetic susceptibility shift is observed in samples that have compartments that are not spherical. BMS shifts depend on differences in the susceptibility, shape, and orientation of each compartment with respect to the magnetic field. BMS shifts are predictable in certain well-defined situations.¹⁸ Based on experiments using parallel coaxial glass cylinders,¹⁸ simple cell suspensions,⁴ and skeletal muscle containing oriented fibers,¹⁹ it is clear that the ^{23}Na spectra of a multicompartiment system in which only some of the compartments contain shift reagent are determined by a combination of hyperfine shift and BMS shifts. The BMS shifts in most biological samples are not predictable. Since the BMS shifts are variable in direction and extent, the net effect is an increase in observed linewidths.²⁰ The shift of intracellular resonances induced by shift reagents in other compartments is a result of the susceptibility shift.

2.1.2 Comparison of Shift Reagents

NMR properties: Each of the shift reagents currently in use to distinguish extracellular Na^+ (Na_o) and Na_i in biological samples produces spectra with both hyperfine and BMS shifts, but their relative contributions differ. For the same concentration of shift reagent, the hyperfine shift is much larger for Dy(PPP)_2^{7-} than for TmDOTP^{5-} , which in turn is larger than for DyTTHA^{3-} . The contribution of BMS shift effects is smaller for TmDOTP^{5-} than for DyTTHA^{3-} . Importantly, at concentrations of 3–10 mM, each of these shift reagents shifts the Na_o signal at least 2–4 ppm, allowing discrimination of Na_o and Na_i signals.

Physiological requirements: Shift reagents must also be compatible with the physiological requirements of the system under study. By assessing cardiac performance (heart rate, aortic pressure, left ventricular pressures) and the contents of the high-energy phosphate compounds ATP and phosphocrea-

tine (or some other sensitive marker) in vivo and in isolated hearts, short-term toxicity has been assessed. Subject to action by phosphatases, $\text{Dy}(\text{PPP})_2^{7-}$ is not stable in most biological samples, yielding free lanthanide which is toxic. Precipitates form at physiological Ca^{2+} concentrations. Consequently, this reagent has limited biological usefulness. Neither DyTTHA^{3-} nor TmDOTP^{5-} disturbs heart function or high-energy phosphate content in isolated hearts provided that care is taken to maintain normal levels of extracellular cations, especially Ca^{2+} . Supplying DyTTHA^{3-} (maximum concentration of 16 mM in blood)²¹ to the living rat had no effects on hemodynamics or high-energy phosphate content of skeletal muscle.¹⁵ Preservation of cardiac function and high-energy phosphate content also supports the conclusion that the sarcolemma is not permeable to these shift reagents, thereby allowing discrimination of Na_i and Na_o .

In summary, TmDOTP^{5-} provides good shifts with little BMS-induced broadening. Its major limitation is loss of solubility with Ca^{2+} levels greater than 1 mM. Nonetheless, TmDOTP^{5-} has been used successfully in the intact rat.^{17,22} DyTTHA^{3-} is quite stable in solutions containing high $[\text{Ca}^{2+}]$. However, it does not offer large hyperfine shifts. Moreover, the DyTTHA^{3-} concentrations employed typically induce bulk magnetic susceptibility shifts, which broadens both the intra- and extracellular resonances. DyTTHA^{3-} has been successfully used in the intact rat,¹⁵ pig,¹⁶ and dog.^{23,24}

2.2 Information Available from ^{23}Na NMS with Shift Reagents for Cations

2.2.1 Information Derived from Changes in Chemical Shift

Information derived from changes in chemical shift of Na_o resonance with time includes kinetics of shift reagent permeation into the tissue and its washout, the extent of perfusion, and the distribution volume of shift reagent. These have been described for skeletal muscle in vivo.^{16,21} The chemical shift of Na_i signal in tissues perfused with shift reagents is small, typically 0.25 ppm; this shift results from BMS effects and does not provide information.

2.2.2 Information Derived from Changes in ^{23}Na Signal Intensities

The Na_o signal is proportional to the amount of Na in all spaces accessible to shift reagent, while the Na_i signal is proportional to the amount of free Na^+ in the compartment(s) not accessible to shift reagent. Electron probe X-ray microanalysis of heart muscle confirms the assumption that almost all cytosolic Na^+ is unbound and also provides evidence that Na^+ is homogeneously distributed through the intracellular space, at least on this scale of measurement. The amounts of Na_i measured by ^{23}Na NMR with shift reagent are the volume-weighted averages over the entire cell population contained within the NMR-sensitive volume. For many tissues, there is significant heterogeneity of cell type; however, for striated muscle, myocytes comprise 80% or more of tissue volume. Therefore, changes in the Na_i signal faithfully report changes in the amount of Na_i in myocytes.

Visibility factor: The amount of Na^+ in any compartment is proportional to the product of its concentration, the volume of

the compartment, and the NMR visibility factor. The NMR visibility factor is the ratio of amount of Na^+ detected by ^{23}Na NMS to the amount measured by other chemical (putatively accurate) techniques. Thus, if volume and visibility factor were known, ^{23}Na resonance areas could be converted to cation concentrations. For this reason, the history of ^{23}Na NMR is replete with attempts to establish both the NMR visibility factor of Na_i and to offer explanations for NMR 'invisibility'.

Published visibility factors for ^{23}Na in biological systems range from 0.1 to 1.0. For a system in which all the Na is the aqua ion and the ion is in a simple bulk solution, the three single quantum transitions of the spin- $\frac{3}{2}$ nuclide are degenerate and the visibility is 1.0. In contrast, for at least some biological systems, it has been thought that only the central transition is visible, yielding a visibility factor of 0.4. Others have suggested that each of the transitions were equally visible or invisible, and, therefore, signal from each transition must contribute equally to the observed signal. In an elegant theoretical and experimental analysis of all six relaxation rate constants of the Na^+ resonance obtained for a single population of isolated spins in fast exchange, Rooney and Springer demonstrated that a major determinant of the so-called 'visibility' is the delay between the hard pulse and enabling of the receiver, the 'dead time'.^{4,25} The shorter the dead time, the higher the visibility factor, i.e. the more of the signal that will be captured. This dependence may explain some of the variability in literature values.

In skeletal muscle, Balschi et al. showed that the visibility factors of the interstitial and intracellular Na are essentially the same or, more precisely, that the visibility of the Na^+ which moves from the interstitium to the intracellular spaces is unchanged.¹⁵ An analogous analysis of the Na^+ signals for the vascular compartment of an isolated perfused heart and its surrounding bath during collapse of the vasculature (caused simply by changing perfusion pressure from 100 to 0 mmHg) showed that the visibility of Na^+ moving from vascular to the bath is not altered by changing environments. Therefore, it is likely that the visibility factors are similar for interstitial and intracellular spaces (probably <1.0) and for vascular and bath (probably 1.0) in a perfused heart. By combining approaches such as these with standard curves, carefully constructed to mimic lossy environments, it should be possible to assess at least changes in visibility factors.

Calculation of concentration: There are two ways of calculating Na_i using ^{23}Na NMR spectra, the ratio method and external standard method. The ratio method takes advantage of the simultaneous measurement of Na_o and Na_i signals in ^{23}Na spectra with shift reagent. Rooney and Springer provide a strategy to quantitate intracellular sodium area (see their Figure 8c and discussion).⁴ Briefly they recommend that the total resonance area of Na_i and Na_o be integrated, curve resolution being employed to integrate Na_i . The Na_i area should then be multiplied by 2.5 (this analysis predicts that only the central resonance, the $\frac{1}{2} - \frac{1}{2}$ transition, is accurately quantified) to provide the total Na_i area and this area subtracted from the total to provide the Na_o area.⁴ The value of Na_i can be calculated using the relationship:

$$\frac{A_{\text{Na}_i}}{A_{\text{Na}_o}} = \frac{[\text{Na}^+]_i V_i v_i}{[\text{Na}^+]_o V_o v_o} \quad (1)$$

where A_{Na_o} is the shifted peak area, A_{Na_i} is the unshifted resonance area, $[Na^+]_i$ is intracellular Na^+ concentration, $[Na^+]_o$ is extracellular interstitial Na^+ concentration, V_i is the intracellular volume, V_o is the extracellular volume, v_i is the visibility of Na_i and v_o is the visibility of Na_o . Solving for $[Na^+]_i$ yields:

$$[Na^+]_i = \frac{A_{Na_i} V_o v_o [Na^+]_o}{A_{Na_o} V_i v_i} \quad (2)$$

The ratio method is appropriate for surface coil experiments where the NMR-sensitive volume has an irregular shape. In experiments where the sample is entirely contained in the NMR-sensitive volume, an external or reference standard may be used to relate area to amount. In this case, the visibility of the compartments reported by Na_o and Na_i must be known.

In both cases, the volume of each compartment must be known. For some tissues, such as resting skeletal muscle, there is good agreement in the literature. However, for isolated organs, there is little or no information about the magnitude of the vascular bed during perfusion or how it changes with time and intervention. The approach described by Clarke and colleagues using ^{31}P -NMR to measure phenylphosphonate and dimethylmethylphosphonate in the total and extracellular water spaces in vivo provides a means to solve this problem.^{26,27} Another method to measure volumes is to use TmDOTP⁵⁻ as a combined cation shift reagent and extracellular space marker, thereby allowing quantification of $[Na^+]_i$ in vivo by NMR.^{28,29}

Results from both NMR and classical experiments show that $[Na^+]_i$ differs for different striated muscles for a given species: 5 mM for rat skeletal muscle by NMR¹⁵ and 10 mM by neutron activation analysis³⁰ versus ~15 mM for rat heart by ion-selective electrodes.³¹ Even for the same tissue, $[Na^+]_i$ differs among species: $[Na^+]_i$ in the hearts of rat, rabbit, and guinea pig are 15, 10, and 10 mM, respectively (note that these estimates assume the visibility factor is 0.6). A more complete comparison of $[Na^+]_i$ determined by classical techniques and by ^{23}Na NMR for heart has been recently summarized.³²

3 APPLICATION OF ^{23}Na , 7Li , ^{39}K , AND ^{87}Rb MRS TO STRIATED MUSCLE: DEFINING CATION MOVEMENTS DURING ISCHEMIA IN THE RAT HEART

Cation MRS with and without shift reagents has been used to measure intra- and extracellular Na^+ , Li^+ , K^+ , and Rb^+ contents. Many studies have examined cation changes during total global ischemia (i.e. zero flow) in isolated hearts of small mammals, typically rats. We have also examined changes in Na_i in the intact heart of the open chest pig and dog during regional ischemia. We illustrate these applications with several examples.

In the submerged isolated heart, there are five major spatial compartments that contain cations: the intracellular space, the extracellular space, the coronary vasculature, the cardiac chambers (atria and ventricles), and the volume outside the heart within the NMR tube, which we term the bath. For all calculations with this model, we assumed that the extracellular (interstitial, vascular, and chamber) ion concentration, $[ion]$,

was equal to the perfusate ion concentration during preischemia and reperfusion. For the rat heart during buffer perfusion at 37°C and 100 mmHg pressure we used the following volumes: V_i 0.48 ml g⁻¹ blotted weight and V_o 1.45 ml g⁻¹ blotted weight.²⁶

3.1 MRS of ^{23}Na

3.1.1 Isolated Heart Studies

The basic protocol consisted of 28 min perfusion with buffer containing the shift reagent followed by 28 min of total global normothermic ischemia. The heart was bathed with ion-free buffer containing shift reagent and mannitol under control of a separate pump. The bath was used to minimize cation signal from the bath. Use of shift reagent in both the Krebs-Henseleit perfusion fluid and the mannitol bath separated the signals from Na_i and Na_o (Figure 3a). The broad resonances underlying the heart signals, ranging from 0 to 9 ppm, represent Na^+ in the mannitol-containing bath, whereas the large shifted peaks, at 1.2–5 ppm, represent buffer Na^+ in the vascular, chamber, and interstitial spaces of the heart (Na_o). The small upfield shoulder on the shifted peak at 1.2–0 ppm represents the resonance of Na_i .

During zero-flow ischemia, the large shifted peak (Na_o) moves ~2 ppm downfield because of the movement of Na^+ from the myocardial vasculature and chambers to the mannitol bath. The area of this peak decreases during the course of ischemia; concomitantly there are progressive increases in the areas of Na_i resonance and in the shifted resonances of the bath. Using the peak areas from the spectra shown in Figure 3a, we estimate that by 28 min of ischemia the Na_i signal increased to 3.6 times the preischemic values: from 9.1 ± 1.3 mM (uncorrected for visibility factor) in the preischemic rat heart to 32.1 ± 1.2 mM at 28 min ischemia. During this time, 79% of the extracellular Na^+ signal moved from the heart to the bath. Assuming that the only water movement was from the heart to the bath and that no water moved from the extracellular to the intracellular space during ischemia, the changes in $[Na^+]_i$ and V_o allow calculation of the changes in $[Na^+]_o$, which decreased from 144 mM in the preischemic heart to 108 mM after 28 min ischemia. Therefore, the ratio of $[Na^+]_o$ to $[Na^+]_i$ during preischemia was 16 (144/9.1) and after 28 min ischemia was 3.4 (108/32). Using the calculated values for $[Na^+]_o$ and $[Na^+]_i$ in the Nernst equation, these data show that $[Na^+]_i$ in the preischemic heart would be in electrochemical equilibrium with a membrane potential of +74 mV.

A number of studies have attempted to define the Na^+ -transport mechanisms during global ischemia in the isolated rat heart. During both low- and zero-flow ischemia, Na_i did not increase in hearts treated with the Na^+/H^+ exchange inhibitor, 5-(N-ethyl-N-isopropyl) amiloride (EIPA).³³ During reperfusion recovery, left ventricular developed pressure was improved for zero-flow hearts treated with EIPA. These studies show that Na^+/H^+ exchange is an important mechanism for Na_i accumulation during myocardial ischemia.^{33,34} After 10 min of global ischemia, lidocaine, a class IB fast Na^+ channel blocker known to protect ischemic myocardium, resulted in lower $[Na^+]_i$.³⁵

Other studies have attempted to define the Na^+ -transport mechanisms during reperfusion following ischemia. A study that tested the effects of limiting Na^+-K^+ ATPase activity

Figure 3 (a) Sodium-23 NMR spectra of an isolated buffer-perfused rat heart showing the increase in intracellular Na^+ (Na_i) during 28 min total, global ischemia. Spectra were acquired using a pulse angle of 90° and a recycle time of 250 ms. Each spectrum consisted of 240 FID, providing a time resolution of 1 min. The spectral width was ± 2 kHz and 1000 data points were collected. Prior to Fourier transformation, the data were multiplied by a double exponential function ($DM = 12$, GE software) for resolution enhancement. (b) An offset stacked plot of ^{23}Na NMR spectra obtained from the in situ pig heart after infusion with the shift reagent DyTTHA^{3-} . The spectra are displayed from the preischemia (front), ischemia, and postischemia (rear) periods. The ^{23}Na NMR resonances of extracellular Na^+ (Na_o) and of intracellular Na^+ (Na_i) are identified

with ouabain found that Na_i^+ increased upon reperfusion in hearts treated with ouabain³⁶ but did not increase if EIPA was also added to inhibit Na^+/H^+ exchange. This indicates the existence of a Na^+/H^+ exchange-mediated Na^+ influx upon reperfusion, which is usually masked by Na^+/K^+ ATPase activity. Another recent study has shown that altering the $[\text{Ca}^{2+}]_o$ can modify the rate at which Na_i decreases during reperfusion. Following reperfusion, low $[\text{Ca}^{2+}]_o$ slowed the decrease in Na_i while high $[\text{Ca}^{2+}]_o$ accelerated the decrease in Na_i .³⁷ This implicates the role of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger in reperfusion ion movements.

3.1.2 Intact Animal Studies

Isolated cells and perfused hearts are relatively well-controlled systems. There are, however, many differences between isolated systems and the in situ heart. The technical difficulty of accurately measuring Na_i in an intact heart is perhaps the main reason that few of these values for the in situ heart exist. We tested the hypothesis that Na_i increases during regional reduced pressure ischemia in the in situ pig heart. Using ^{23}Na NMR in combination with the shift reagent DyTTHA^{3-} the Na_o and Na_i contents of the pig heart could be distinguished (Figure 3b). We estimated a $[\text{Na}^+]_i$ of 7 mM for the pig left ventricle prior to ischemia.¹⁶

In a model of reduced-pressure regional ischemia, Na_i did not change during the first 18 min of ischemia with Na_i set to 1 for preischemia. Subsequently, Na_i increased from 1.3 at 22 min to 1.6 at 38 min, the end of ischemia. Levels remained el-

evated during early reperfusion; after 10 min of reperfusion Na_i had increased further to 1.9. This increase of Na_i and its delayed recovery during postischemia did not arise from insufficient reperfusion because phosphorylated metabolites, measured by concomitant ^{31}P NMR, all rapidly recovered during early reperfusion while Na_i was increasing. This remarkable response of Na_i to reperfusion may reflect enhanced Na^+ influx, possibly by Na^+/H^+ exchange, with or without reduced Na^+/K^+ ATPase efflux. Levels of Na_i returned to preischemia values at 18 min of reperfusion.¹⁶

3.2 MRS of ^7Li

Lithium-7 is 93% abundant with an NMR sensitivity that is twice that of ^{23}Na (Table 1). These NMR properties, combined with the ability of Li^+ to replace Na^+ in the fast Na^+/H^+ exchanger (see Figure 1) makes ^7Li MRS a useful tool to study Na^+ movements in biological samples.

Lithium-7 MRS has been used to show that the Na^+/H^+ antiporter contributes to net Na^+ influx during ischemia in isolated perfused hearts.³⁸ Fully relaxed ^7Li NMR spectra [such as shown in Figure 4(a)] were acquired throughout the protocol. The kinetics of Li^+ uptake were determined by perfusing hearts with a buffer containing 78 mM Li^+ .

Movement of Li^+ into the intracellular space of the heart is monoexponential with a rate constant of 0.068 min^{-1} , a $t_{1/2}$ value of 10.3 min, and an initial rate of increase of 5.27 mM min^{-1} . The Li^+ concentration after 24 min of control perfusion was $57 \pm 7 \text{ mM}$. ICP-AES analysis gave an intracellular Li^+

concentration of 50 ± 2 mM after 20 min perfusion showing that NMR visibility was approximately 1. Uptake in the well-perfused heart was unaffected by the Na^+/H^+ exchange inhibitor amiloride. At the end of the 28 min ischemia, $[\text{Li}]_i$ was 84 ± 10 mM. Amiloride completely prevented the uptake of Li^+ that occurred during ischemia, showing that Na^+/H^+ exchange contributes importantly to the increase in Na_i during ischemia.

3.3 MRS of ^{39}K

The ^{39}K NMR spectrum of a rat heart perfused with buffer containing shift reagent has two well-defined peaks: a large intracellular K^+ resonance and a smaller downfield extracellular resonance, the area of which is proportional to the sum of K^+ in the vascular, interstitial, and bath spaces [Figure 4(b)]. The areas of both signals remained constant throughout control perfusion. During control perfusion the K_i signal comprised 74% of the total ^{39}K signal.

During ischemia, the vasculature collapses within minutes (owing to zero perfusion pressure) and perfusate is extruded into the bath. Hence, the extracellular compartment in exchange with the intracellular compartment is primarily the interstitium. Accordingly, the interstitial K^+ signal can be calculated as the difference between the sum of vasculature and bath K^+ signals and the total extracellular K^+ signal. By 28 min of ischemia, there was no detectable change in $[\text{K}^+]_i$ but interstitial $[\text{K}^+]$ decreased. The change corresponded to an increase in the potassium membrane potential from -88 mV to -46 mV.

3.4 MRS of ^{87}Rb

Rubidium-87 is a well-established congener for K. Relatively high natural abundance and high NMR sensitivity combined with low biological abundance make ^{87}Rb a good tracer for K^+ influx and efflux studies. Unlike ^{23}Na or ^{39}K NMR studies where changes in steady-state concentrations are measured with the aid of shift reagents, the rates of influx (in the presence of extracellular Rb^+) and efflux (in the absence of extracellular Rb^+) have been measured in the absence of shift reagents.

Measured rates of influx of Rb^+ have been used to estimate Na^+/K^+ ATPase activity in living tissues using radioisotopes, atomic absorption spectroscopy, and MRS. It has been shown using ^{87}Rb MRS that, under normal physiological conditions, Rb^+ influx occurs mainly through Na^+/K^+ ATPase; the contribution of the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter and K^+ channels to Rb^+ influx is small.³⁹ Therefore, ^{87}Rb NMR can be used to assess the activity of the Na^+/K^+ ATPase in the perfused heart under normal and ischemic conditions.⁴⁰

4 SUMMARY

MRS with ^{23}Na and ^{39}K in combination with shift reagents allows measurement of intra- and extracellular $[\text{Na}^+]$ and $[\text{K}^+]$ in biological systems. The use of ^{87}Rb MRS provides a measurement of Na^+/K^+ ATPase activity. These techniques provide unique information on the transmembrane movements of Na^+ and K^+ in intact tissues.

Figure 4 (a) Lithium-7 NMR spectra of a rat heart perfused with buffer containing shift reagent and 78 mM Li^+ (intracellular Li^+ , Li_i ; extracellular Li^+ , Li_o). Spectra were acquired at 8.34 T using a pulse angle of 90° and a recycle time of 45 s. Each spectrum consisted of 8 FID, providing a time resolution of 6 min. Prior to Fourier transformation, the data were multiplied by an exponential function giving a line broadening of 10 Hz for resolution enhancement. (b) Potassium-39 NMR spectra of a rat heart perfused with buffer containing the shift reagent $\text{Dy}(\text{TTHA})^{3-}$ (intracellular K^+ , K_i ; extracellular K^+ , K_o). Spectra were collected as described as in Figure 3. (Reproduced by permission of Springer-Verlag from J. S. Ingwall, 'Magnetic Resonance (MR) Imaging', 2nd ed., 1992, p. 131)

Approx. 160 publications. Current research interests: regulation of cardiac energy metabolism and cation transport using ^{31}P and ^{23}Na NMR spectroscopy.

Cells and Cell Systems MRS

Jerry D. Glickson

The Johns Hopkins University School of Medicine, Baltimore, MD, USA

1 INTRODUCTION

Magnetic resonance spectroscopy (MRS) of cells and cell systems (or cellular MRS) includes studies of intact living cells or assemblies of cells. Perfused organs and tissues, and cell extracts are not included in this topic (see *Tissue and Cell Extracts MRS*).

A key advantage of cellular MRS is that it can be conducted under well-defined and well-controlled conditions that generally cannot be achieved in the intact organism. The cellular model is often designed to facilitate the interpretation of in vivo MRS data. Systemic physiological effects, which often limit the interpretation of in vivo MRS, are absent in ex vivo cellular studies or can be systematically simulated and evaluated. However, some applications of cellular MRS focus on issues unique to the cellular system, e.g. characterization of bioreactors for production of various biological products, cell preservation, artificial organs, and microbiological studies. The range of cell systems that have been examined includes isolated bacteria and other prokaryotes, yeast, plant cells, mammalian cells, and even giant single mammalian cells. In most instances the goal is to study a uniform cell population; however, the effects of heterogeneity can be systematically investigated using multicellular assemblies such as tumor spheroids or renal microtubules. Subcellular organelles such as mitochondria and chromaffin granules have also been investigated. A variety of nuclear species have been monitored, including ^1H , ^2H , ^3H , ^7Li , ^{13}C , ^{15}N , ^{19}F , ^{23}Na , ^{31}P , ^{39}K , and ^{133}Cs , the main limitation being sensitivity and cost.

A number of excellent reviews of cellular MRS have been published.^{1,2} We will limit ourselves to a description of key methods, their advantages and disadvantages, and will also present a few examples of important applications. We will note some recent developments that permit noninvasive discrimination between intracellular and extracellular metabolites. Finally, we will evaluate the potential of this method, and indicate possible areas for development.

2 PROBE DESIGN

2.1 Cell Suspensions

Early cellular NMR studies were performed on unstirred high-density suspensions of cells in conventional NMR tubes. Cells were often cooled in order to preserve viability. Spectral quality was generally poor, and cells died as substrates were depleted and toxic waste products accumulated.

These methods were most suitable for nonoxygen-dependent cells that can tolerate high cell densities, such as red blood cells and anaerobic bacteria. Despite these limitations, the early studies demonstrated the potential utility of in vivo measurements of cellular metabolism.

The first cellular NMR studies were ^{13}C NMR measurements by Matwiyoff's laboratory on suspensions of blood cells³ containing ^{13}C -labeled CO_2 , CO , and CN^- and on the metabolism of $[1-^{13}\text{C}]$ glucose by yeast.⁴ Moon and Richards⁵ first demonstrated the ability of ^{31}P NMR to measure intracellular pH from the chemical shift of the 2,3-diphosphoglycerate (DPG, an intracellular metabolite) peaks and from the intracellular inorganic phosphate (Pi) resonance. Shulman's group at Bell Laboratories and later at Yale University initiated ^{31}P and ^{13}C studies of energy and carbohydrate metabolism, sodium transport and pH regulation in bacteria,^{6,7} yeast,⁸ liver cells,⁹ and cultured tumor cells.¹⁰ These studies had a seminal influence on the development of in vivo NMR spectroscopy, and demonstrated the unique ability of this method to examine key metabolic processes noninvasively.

Bubbling of oxygen into the NMR tube was introduced in order to oxygenate and stir the suspension, but the timing of spectral accumulations had to be adjusted to avoid intervals when bubbles were in the tube. Some of the limitations of these early methods could be overcome by using larger chambers equipped with mechanical stirrers and provided with ports for delivery of gases and sensors for monitoring temperature and $p\text{O}_2$; cells were examined at 37°C for up to 2 h.^{11,12} Placement of the receiver/transmitter coil inside the sample volume¹² improved sensitivity, but the apparent relaxation times were dependent on the mixing rate. Another variation of this approach is the 'airlift chamber'.^{13,14} This assembly consists of a large NMR tube with a smaller-diameter concentric tube (open at both ends) inside it. A rapid stream of oxygen bubbles is delivered through a capillary located above the region of the receiver coil. This oxygenates the cells without introducing bubbles into the sampling region and causes efficient circulation of the cell suspension. Taylor and Deutsch¹⁵ compared the airlift probe with a flow cell assembly for measuring oxygen concentrations and pH in suspensions of *Paracoccus denitrificans* (see Section 3.2). Since spectral characteristics, particularly relaxation times, depend on flow rate and bubble size, the flow and airlift systems have to be recalibrated for each experiment.

In summary, the key limitation of suspension systems is that they are applicable only to nonanchorage-dependent cells; they do not control the concentration of oxygen and vital substrates, and they allow toxic metabolic end-products to accumulate. Bubbling oxygen through the cell suspension, or mechanical stirring, often causes damage to fragile cells and modifies relaxation rates.

2.2 Perfusion Systems

2.2.1 General Characteristics

The solution to most of these problems is a perfused cell system, which allows long-term experiments to be performed on isolated cells, cell aggregates, or small organisms under conditions of well-defined medium composition. The system consists of an NMR probe in which the cells are retained by

attachment to beads, entrapment in a gel, or containment in a chamber with a semipermeable membrane. The perfusion system is attached to a reservoir that provides medium at a fixed temperature, usually 37 °C. For reasons of economy, recirculating systems are preferred when an expensive medium containing isotopically enriched substrates or expensive drugs is used. The recirculating system is adequate provided its capacity is large enough to prevent depletion of substrates or accumulation of toxic waste products; alternatively, a single-pass delivery system can be employed. Provision is generally made for delivery of gases, usually 5% CO₂/95% O₂ or air. Sterility should be maintained throughout the experiment by sterilizing the media and perfusion system, and by using large-capacity filters or closed systems. Perfusion systems have been designed for studies of both anchorage-dependent and anchorage-independent cells. Ng et al.¹⁶ have constructed a system suitable for γ -irradiation of cells directly in the NMR tube without interruption of perfusion.

2.2.2 Microcarrier Beads

In 1981, Ugurbil et al.¹⁷ introduced the first perfusion system for NMR investigation of anchorage-dependent cultured mammalian cells. Normal and transformed mouse embryo fibroblasts were grown on collagen-coated dextran microcarrier beads; at confluence the cells were transferred into a cylindrical glass chamber fitted with Plexiglas end-pieces containing nylon mesh screen filters for retention of the beads. A four-turn solenoidal coil was fitted around this sample chamber. Theoretically, a solenoid provides a 2.6-fold enhancement in sensitivity over a Helmholtz (saddle) coil.¹⁸ However, in practice at least equivalent spectral quality can be achieved with a simpler system developed by Neeman and Degani¹⁹ which employs a conventional 10 mm NMR tube and uses a commercial high-resolution Helmholtz coil (Figure 1). The improvement in magnetic field homogeneity of this design makes up for the higher intrinsic sensitivity of the solenoidal coil. The perfusate reservoir can easily be replaced for changing the perfusion medium, and the spectrometer can be programmed to monitor various nuclei according to a predefined protocol. Figures 2 and 3 show representative ³¹P (202.5 MHz) and ¹³C (125.7 MHz) spectra obtained with this system.

The key advantage of the microcarrier method is that it maintains cells in a uniform well-perfused state; several days of perfusion can be readily achieved with currently available perfusion probes (see below). The cell density is relatively low, and only a small fraction of the volume of the sample chamber is occupied by the cells (~6%). This improves homogeneity of perfusion since minimal depletion of oxygen and substrates avoids creation of local nutrient gradients.

Cell replication generally occurs, at least until the plateau phase of growth. Finding the proper conditions for attachment of cells to the beads is essential. Beads manufactured from various materials such as polyacrolein, polystyrene, glass, polyacrylamide, and agarose polyacrolein are commercially available. Coating with polylysine or collagen can be used to improve cell attachment. Gelatin beads or dextran beads covered with a layer of denatured collagen (Cytodex 3) are enzymatically degradable, which facilitates recovery of cells for assay of cell number and viability. Disadvantages of the microcarrier bead system include that it has relatively low

Figure 1 Schematic of perfusion system developed by Neeman and Degani¹⁹ employing a 10 mm outer diameter NMR tube as the perfusion chamber. Figure 3 Carbon-13 NMR spectra of T47D-clone 11 (6.0×10^7) cells treated with estrogen as in Figure 2 after 1 h perfusion with medium containing $[1-^{13}\text{C}]$ glucose. Spectra were Fourier transformed using 10 Hz line broadening. The designated glucose signals are due to nonenriched carbons of the glucose in the medium. (Reproduced by permission of American Association for Cancer Research, Inc. from Neeman and Degani¹⁹)

spectral sensitivity, that it is limited to anchorage-dependent cells, and that exposure to cytotoxic agents (e.g. cancer drugs) can detach cells from the beads. Smaller beads increase the total cell volume and, hence, increase spectral sensitivity.

2.2.3 Gels

Cells have been immobilized by encapsulation in a variety of gelatinous materials. Encapsulation is usually simpler than attachment to microcarrier beads, and is applicable to anchorage-independent as well as to anchorage-dependent cells. An important advantage for studies of therapeutic agents is that encapsulation of the cells prevents cell detachment as a result of exposure to cytotoxic agents such as cancer drugs or γ -irradiation. The porosity of the matrix determines the rate of diffusion of substrates and metabolic end-products. The gel may also modify cellular growth characteristics. Preparation of cells for encapsulation in the gel can involve treatment with enzymes to isolate them from the primary culture system and exposure to low temperature. These procedures may modify important cellular characteristics. Removal of cells from the gel in a viable state suitable for clonogenic assay (ex vivo measurement of cellular capacity to replicate) can in some instances be difficult.

2.2.4 Agarose Threads or Beads

This method was first introduced by Foxall and Cohen in 1983.²⁰ Cells are mixed with liquid agarose in phosphate-buffered saline, and placed in a bath at 37°C for 5–7 min to form a gel. The mixture is extruded under low pressure through 0.5 mm internal diameter tubing in an iced bath into an NMR tube containing growth medium. The solid threads are concentrated without compression at the bottom of the tube by a plastic insert. Perfusion is maintained by a peristaltic pump, and the system is aerated by diffusion of air through Teflon tubes in the system. The system is stable for more than 24 h when perfused with whole growth medium.

The agarose threads are permeable to proteins such as albumin and also to various polypeptides, thus permitting investigation of their effects on cellular metabolism and growth characteristics. The system is suitable for encapsulation of yeast, bacteria, protozoa, and a variety of mammalian cells. Small anchorage-independent cells such as lymphocytes tend gradually to wash out of (0.9%) agarose gel threads.¹ Additional limitations include the requirement for cooling cells in an ice bath and reduced cell growth rates in the agarose threads.

Encapsulation of cells in agarose beads is accomplished by mixing the cell suspension with warm liquid agarose and dispersing the suspension in paraffin oil with magnetic stirring. The mixture is cooled in an ice bath after the droplets have formed, to produce small solid cell-containing capsules, which are collected by centrifugation and placed in an appropriate medium and NMR perfusion system. This method has been used for studies of microorganisms, plant cells, and algae.¹ Entrapment in agarose did not alter metabolism, and allowed cells to proliferate. Lymphocyte proliferation has been examined in 3% agarose gel beads, but beads composed of 1.2% agarose were unstable.²¹ Mouse hybridoma cells encapsulated in agarose were metabolically active and produced monoclonal antibodies.¹

2.2.5 Matrigel

Growth rates of anchorage-dependent cells comparable with in vivo rates (of tumor cells) can be achieved by using a basement membrane matrix preparation extracted from a mouse tumor line (commercially available as Matrigel).¹ Cells are introduced into the liquid Matrigel in an ice bath; the suspension is warmed to 37°C to form a gel, which is extruded through tubing to produce threads. Typically, threads are prepared at low cell density, and cells are allowed to grow in the threads before examination. Normal cells grown in Matrigel become morphologically and functionally similar to their in vivo counterparts; tumor cells simulate in vivo tumor cell growth, producing a high-density model tumor Figure 4. Nonuniform perfusion occurs in later stages of tumor growth, as it does in in vivo tumors and in spheroids (see below).

2.2.6 Alginate Beads

Narayan et al.²² introduced a method for NMR studies of perfused tumor cells encapsulated in calcium alginate beads. Cells isolated from monolayer culture by trypsinization are suspended in a sodium alginate solution; beads form when droplets of this suspension are introduced into a CaCl_2 solution. The beads are washed with fresh medium and perfused in a system similar to the one depicted in Figure 1.

Cells perfused in alginate retain stable levels of phosphate metabolites for at least 72 h of perfusion. Some cells replicate in this medium; however, RIF-1 tumor cells do not replicate at the high cell densities used for NMR studies (7×10^7 cells/mL), even though they do at lower cell densities. Furthermore, RIF-1 tumor cells recovered by dissolving the alginate beads with sodium citrate do not retain clonogenic capacity. Exposure of cells to high concentrations of calcium could be responsible for loss of proliferative capacity.

Figure 4 MDA-231 breast cancer cells growing in Matrigel threads (500 μ M diameter). (Reproduced by permission of Springer-Verlag from Kaplan et al.¹)

Tumor cells, plant cells, and algae have been investigated.¹ Lymphocytes, which are too small to be retained in (0.9%) agarose threads (see above), can be studied in alginate beads.

McGovern et al.²³ introduced a technique for monitoring oxygen concentration during NMR experiments by incorporating perfluorocarbons into the alginate cell suspension. The ^{19}F spin-lattice relaxation rate of the perfluorocarbon indicates the average oxygen concentration (see Section 3.2). Mathematical modeling permits estimation of the oxygen gradient within the alginate beads. This method could readily be adapted for measuring rates of oxygen consumption and can be used in any gel-based immobilization system.

2.2.7 Other Immobilization Matrixes

Aiken et al.²⁴ used Cultisphere G-L collagen beads (Hyclone Labs, Logan, UT, USA) for studies of RIF-1 cells. The cells grow within crevices as well as on the surface of the beads. Unlike the alginate system (see above), the collagen beads allow (RIF-1) cells to replicate at a rate equivalent to that in monolayer

culture. Cells are easily recovered by treating the beads with Dispase (Collaborative Research, Bedford, MA, USA); cloning efficiency of RIF-1 is similar to that of cells trypsinized from monolayer culture. This system is suitable for studying the effects of antineoplastic agents during normal cell replication.

Gamcsik (personal communication) has recently employed a 'sponge-like' collagen gel matrix, Spongostan (Ferrostan, Denmark) in NMR studies of perfused MCF-7 tumor cells. This matrix can provide more mechanical stability than Cultisphere G-L beads, which tend to settle out or move around in the perfusion chamber.

2.2.8 Hollow Fibers

The hollow fiber methods, first introduced by Gonzalez-Mendez et al.,²⁵ deliver oxygen and substrate to the cells through a compartment separated from the cells by a semipermeable membrane. These bioreactor systems are described elsewhere in detail. The key advantage of these systems is that they allow very high-density growth of tumor cells, approaching that of intact tissue. This also produces their key deficiency—the development of oxygen, nutrient, and metabolite gradients. These systems are considerably more complex than the immobilization techniques described above. Nonuniform distribution of cells can occur, and it is difficult to access the cells for counting or biological assays during the course of an experiment. However, these are the best systems for very long-term investigations, and they can achieve the highest spectral sensitivity of all the perfused cell systems.

2.2.9 Spheroids

Multicellular spheroids are spherical aggregates of tumor cells, which serve as models of heterogeneously perfused *in vivo* tumors. Cells near the external surface are well perfused, metabolically active, and rapidly proliferating; those further into the interior of the spheroid are relatively poorly perfused and metabolically and proliferatively quiescent; in larger spheroids a central core of necrotic cells is also encountered.

Lin et al.²⁶ introduced a very simple perfusion system for NMR study of spheroids, in which spheroids were allowed to settle at the bottom of a 10 mm NMR tube while perfusate was slowly pumped through the system for up to 80 h. No mechanical restraints were introduced into the system. This system has a number of deficiencies, the most important one being the tendency of spheroids to aggregate, which results in substantial modification of the metabolic and proliferative properties of the tumor cell.

Ronen and Degani²⁷ addressed this problem by encasing small MCF-7 spheroids in agarose beads. Studies were performed in the conventional perfusion system shown in Figure 1. They achieved a very high cell density (10^8 cells/1.5 mL), which permitted measurement of fully relaxed ^{31}P NMR spectra in 7.5 min. Cell growth followed Gompertzian kinetics; decreases in levels of NTP and the rate of production of ^{13}C -labeled lactate (from metabolism of $[1-^{13}\text{C}]\text{glucose}$ monitored by ^{13}C NMR) in the plateau phase were attributed to the development of central necrosis in the spheroids.

Freyer et al.²⁸ have designed an efficient perfusion system for spheroids (Figure 5). It consists of a 20 mm NMR tube equipped with a mechanical stirrer and multiple inlet lines and

Figure 5 Diagram of the spheroid NMR perfusion chamber. The arrows indicate the direction of medium flow. The sensing volume of the NMR coil is indicated by the hatched area in the spheroid chamber. (Reproduced by permission of John Wiley and Sons from Freyer et al.²⁸)

sensors for oxygen concentration, pH, and temperature. EMT6/Ro spheroids are grown in the NMR tube under conditions identical to those employed in batch culture, and exhibit identical growth characteristics, cytokinetic parameters, and clonogenic viability. Except for changes due to cell growth, the system is extremely stable (<5% variation over a 24 h period in the NMR tube or in culture). Transient interruption of perfusion or stirring produces significant, largely reversible, changes in ^{31}P NMR characteristics. The cell density ($\sim 5 \times 10^8$ cells/9.5 mL) is substantially lower than that of the Ronen and Degani system, and the maximum medium flow rate is 34 mL min^{-1} compared with 1.5 mL min^{-1} employed by Ronen and Degani.²⁷ Freyer's system has two additional advantages: (i) the spheroids are uniformly distributed in the perfusion system, and (ii) the spheroids can readily be recovered for cytokinetic and radiobiological assays.

3 SPECIAL METHODS

3.1 Distinction Between Intracellular and Extracellular Metabolites

Distinction between intracellular and extracellular compartments by MRS has been accomplished on the basis of differences in chemical shifts, relaxation times, and diffusion constants of metabolites in these compartments or by the introduction of reagents that are confined to one or another compartment. In most instances this has required the introduction of special reagents, such as paramagnetic contrast agents or exploitation of unique properties of the cellular target (e.g. magnetic field gradients within erythrocytes). A more general approach to this problem which does not require introduction of reagents or unique properties in the target cell is the use of pulsed field gradients. This technique, first introduced by Andrasko²⁹ in 1976 for studies of Li^+ transport into red blood cells, was recently adapted to ^1H NMR studies of perfused cell

systems by van Zijl et al.³⁰ It exploits differences in the effective diffusion constants of intracellular and extracellular metabolites. These investigators employed a diffusion-sensitive stimulated echo pulse sequence to isolate signals from MCF-7 cells encapsulated in agarose threads (see above). By proper choice of gradients and delays, one can determine the ratio of extracellular to intracellular volumes and eliminate the resonances of all the extracellular metabolites, which generally have a larger diffusion constant because they are flowing and are not restricted to the intracellular compartments.

This method could be extended to other nuclei such as ^{19}F , ^{31}P , ^{13}C , and ^7Li , but lower γ -nuclei will require proportionately steeper gradients. These are becoming available on the newer instruments.

3.2 Indicator Compounds

Many cellular parameters cannot be directly measured by NMR. Exogenous reagents have been developed to measure parameters such as intracellular and extracellular pH, concentrations of Ca^{2+} , and Na^+ , as well as redox state, $p\text{O}_2$, cell volume, and membrane potential. Szewergold² has reviewed these, and they will be discussed only briefly here.

3.2.1 pH

Deutsch's laboratory³¹ has developed a variety of fluorinated pH indicators that are trapped inside cells. A variety of other indicators of intracellular and extracellular pH which can be monitored by ^{31}P NMR are also available.²

3.2.2 Calcium Ions

Intracellular calcium concentrations can be monitored by ^{19}F NMR with the fluorinated chelator 5,5'-difluoro-1,2-bis(2-aminophenoxy)ethane- N,N,N',N' -tetraacetic acid (F-BAPTA),³² but the high calcium buffering capacity of this chelator has generated concern about its perturbing effect on cell physiology. F-BAPTA can also bind other divalent cations. The fluorinated chelator is introduced into the cell as a membrane permeable ester and is trapped inside the cell after hydrolysis by endogenous esterases. The calcium concentration is determined from the dissociation constant of the calcium complex of F-BAPTA and the ratio of intensities of resonances of the free and bound chelate.

3.2.3 Magnesium Ions

Intracellular magnesium can be measured from the chemical shift of the β -resonance of ATP, but the K_d is so low that ATP is usually saturated under physiological conditions. 4-Methyl-5-fluoroaminophenol- N,N,O -triacetic acid (MF-APTRA) and 5-fluoroaminophenol- N,N,O -triacetic acid (5F-APTRA) are fluorinated chelators with considerably greater promise because of their lower dissociation constants.²

3.2.4 Sodium Ions

Paramagnetic shift and relaxation reagents have been used to distinguish intracellular from extracellular sodium ions,^{33,34} but these agents can be toxic and some are slowly degraded on long-term contact with cells (see **Cation Move-**

ments across Cell Walls of Intact Tissues Using MRS). These problems can be avoided by not recycling the shift reagent (G. Elgavish, personal communication). The use of multiple quantum coherence methods to distinguish intracellular sodium has been proposed;³⁵ however, extracellular sodium ions that are immobilized by interaction with a gel matrix or with cell surfaces at high cell densities may also exhibit multiple quantum coherence transfer and, hence, be indistinguishable from intracellular sodium ions.

3.2.5 Redox Potential

Redox potentials can be determined from the ratio of oxidized to reduced forms of metabolites, using the Nernst equation and the standard reduction potential of the couple. This principle has been applied to a variety of ¹³C-labeled couples, including lactate/pyruvate, β -hydroxybutyrate/acetoacetate, NAD(P)/NAD(P)H, and the reduced and oxidized forms of the radiation sensitizer WR3689.²

3.2.6 Oxygen

The increase in the spin-lattice relaxation rate due to paramagnetic oxygen molecules, $1/T_{1P}$, varies linearly with oxygen concentration. With proper calibration the oxygen concentration can be determined from measurements of T_{1P} of the ¹⁹F resonance of perfluorocarbons.^{15,23}

3.2.7 Membrane Potential

Membrane potentials are calculated from the ratio of intracellular and extracellular metabolites, which are in slow exchange on the chemical shift timescale. The membrane potential of erythrocytes has been measured by ³¹P NMR using the hypophosphite ion as a probe; trifluoroacetate was employed in a ¹⁹F NMR study.²

3.2.8 Cell Volume

Cell volume has been measured by ³¹P and ¹⁹F NMR, using dimethyl methylphosphonate or trifluoroacetamide as an extracellular probe, and also by ²³Na NMR, by utilizing the low concentration of intracellular compared to extracellular sodium.²

4 APPLICATIONS

Below we present a few examples of cellular NMR studies which illustrate the versatility of this method. They demonstrate its utility for studying fundamental principles of bioenergetics, for investigating mechanisms of antineoplastic agents in tumor cells, for elucidating biochemical pathways, and for evaluating mechanisms underlying therapy-induced in vivo spectral changes in tumors.

4.1 Cell Suspensions

4.1.1 The Chemiosmotic Hypothesis

As originally proposed by Mitchell,³⁶ certain membranes of microorganisms and organelles (such as mitochondria and

chloroplasts) are impermeable to protons. Oxidation of substrates via the electron transport chain results in transport of protons across these membranes, generating an electrical potential ($\Delta\psi$) and a pH gradient that are coupled to the free energy, ΔG_{ATP} , for the ATP synthase reaction ($Pi + ADP \rightleftharpoons ATP$) by the equation

$$\Delta G_{ATP} = -nF \Delta\psi + 2.3nRT \Delta pH \quad (1)$$

where F is the Faraday constant, and n is the number of protons transported per ATP molecule synthesized. When the ATP synthase-mediated reaction runs in the forward direction, protons are transported back across the membrane so as to collapse the electrochemical potential.

Ugurbil et al.⁶ used ³¹P NMR simultaneously to measure changes in ΔpH and in phosphorylation potential ($[ATP]/[ADP][Pi]$) in *Escherichia coli* cells grown on succinate or glucose under aerobic and anaerobic conditions. Effects of ATPase inhibitors and ATPase-deficient mutants and uncouplers were investigated. These results, together with independent determinations of the membrane potential,³⁷ were in qualitative agreement with equation (1), providing confirmation of the chemiosmotic hypothesis.

4.2 Perfused Cells and Spheroids

4.2.1 Cyclophosphamide Metabolism

Cyclophosphamide (**1**) is a potent alkylating agent used in the treatment of a wide range of human cancers. The key steps in the metabolism of this drug are depicted in Figure 6. In the liver, microsomal oxidation of (**1**) produces 4-hydroxycyclophosphamide (**2**), which is subsequently converted to aldophosphamide (**3**) in the tumor. The latter is converted to acrolein (**5**) and phosphoramidate mustard (**4**), the active species which cross-links DNA. Boyd et al.³⁸ measured the apparent rate of alkylation of DNA in perfused tumor cells immobilized in agar threads. They incorporated (**2**) into the perfusate, monitored its conversion into (**3**) and (**4**), and then eliminated (**2**) and (**3**) by washing the cells with drug-free perfusate. Subsequent disappearance of (**4**) followed first-order kinetics, and was attributed to formation of an NMR-invisible adduct of DNA. While drug concentrations were in the millimolar range, well above clinical levels, this experiment demonstrates the unique ability of NMR spectroscopy to monitor complex pharmacological reactions inside intact tumor cells.

4.2.2 Phospholipid Metabolism

Ronen and Degani³⁹ have used ³¹P and ¹³C NMR spectroscopy to examine the effect of spheroid size on the metabolism of phospholipids. The largest variations occurred in levels of the phospholipid precursors, phosphocholine (PC) and phosphoethanolamine (PE). Phosphatidylcholine (PhCh) is synthesized via the Kennedy pathway by which choline is phosphorylated to PC by choline kinase, then PC is combined with cytosine triphosphate (CTP) via the action of CTP-phosphocholine transferase, forming cytosine diphosphocholine, which then combines with diacylglycerol (DAG) to form PhCh. Although phosphatidylethanolamine (PhEt) can be synthesized from PE via the Kennedy pathway, if ethanolamine is limiting, an alternative pathway, decarboxylation of phosphati-

Figure 6 Generally accepted scheme for the metabolism of cyclophosphamide in the liver and tumor cells. (Reproduced by permission of American Chemical Society from Boyd et al.³⁸)

dyserine, may be used. The reaction effectively converts serine (which is abundant in most media) into ethanolamine, which can then be used for synthesis of PhEt.

To monitor the kinetics of these reactions Ronen and Degani³⁹ grew T47D human breast spheroids in the presence of [1,2-¹³C]choline, and [1,2-¹³C]ethanolamine and [3-¹³C]serine. The specific pathway for phospholipid metabolism could be deduced from the labeling pattern of the metabolites in cells and in lipid extracts. They found that the ratio of PhCh to PhEt was independent of spheroid size, but the rates of the reactions in the Kennedy and serine decarboxylase pathways varied with the availability of substrates. The serine decarboxylase reaction decreased with increasing ethanolamine in the medium, and increased with spheroid size; the latter effect was attributed to decreased permeability of large spheroids to exogenous ethanolamine.

4.2.3 Mechanism of Chemotherapy- and Radiation-Induced MRS Changes in In Vivo Tumors

During untreated growth, most transplantable tumor models in rodents exhibit a progressive decline in their bioenergetic status, a decrease in levels of high-energy phosphates compared with low-energy phosphates and an acid shift in pH (see *Spectroscopic Studies of Animal Tumor Models*).^{16,24} When treated effectively with radiation or a number of chemotherapeutic agents, many of these tumors exhibit an anomalous reversal of this pattern which does not simply reflect a decrease in tumor size. These metabolic changes could result from direct effects on cellular metabolism or they could result from 'tissue

effects' (changes in perfusion, cell density, etc.). To evaluate direct effects on cellular metabolism, Ng et al.¹⁶ and Aiken et al.²⁴ examined the effects of γ -irradiation and of chemotherapy with 4-hydroperoxycyclophosphamide (an active derivative of cyclophosphamide), respectively, on RIF-1 cells perfused after immobilization on alginate beads or Cultisphere G-L beads (see above). The in vivo effects of these agents were not observed in the perfused cells. In fact, radiation induced a decline in bioenergetic status prior to cell death. The duration of these experiments corresponded to the timescale over which the bioenergetic 'improvements' were observed in the in vivo tumor. These data suggest that 'tissue effects' are responsible for the changes induced in this tumor by radiation and chemotherapy in vivo. This conclusion is consistent with reports that increases in tumor blood flow are correlated with radiation- and chemotherapy-induced improvements in tumor bioenergetic status.^{16,24}

5 SUMMARY AND FUTURE DIRECTIONS

A wide variety of perfusion systems are available to support various applications of NMR spectroscopy to the study of cellular metabolism. Each method has distinct advantages and limitations. The particular system should be chosen to meet the needs of the application. The key advantage of NMR methods is that they permit investigation of metabolism in the intact cell. The key disadvantage of all NMR methods is limited spectral sensitivity. The examples we have chosen illustrate the utility of the method for investigation of key metabolic processes and for elucidation of mechanisms underlying in vivo spectral changes.

It is likely that major technical advances such as the use of gradient-based methods to discriminate intracellular and extracellular compartments described above will be employed in studies of cellular transport and metabolism. Multiple quantum editing techniques and imaging methods to measure diffusion constants and flow will probably be used in future cell studies. Isotopes such as ¹⁵N and ¹⁷O should receive more attention. Tagging of cells, multicellular organisms, or organelles with paramagnetically or isotopically labeled reagents may be used to follow embryonic development. Specialized NMR probes for monitoring oxygen in the concentration range relevant to radiation biology and respiration are likely to be developed (see *EPR and In Vivo EPR: Roles for Experimental and Clinical NMR Studies*). Molecular biological techniques will doubtlessly have a major impact on cellular NMR studies. Overall, the field of cellular MRS, like the other MR fields, is undergoing very rapid development and is likely to continue to do so for some time.

Spectroscopic Studies of Animal Tumor Models

Simon P. Robinson, Cheryl L. McCoy, and John R. Griffiths

St George's Hospital Medical School, London, UK

1 INTRODUCTION

In the clinic, there are practical constraints on what can be done to study tumors in patients as well as ethical considerations, i.e. an untreated tumor cannot be monitored through growth. Animal tumor models allow studies of basic tumor biology, metabolic stress, and response to therapeutic regimes in large enough numbers to obtain statistical significance. For basic, routine cancer research a regular supply of reproducible tumors is required. Many tumor models have been developed; the majority are grown subcutaneously in standard laboratory rodents, and are well characterized and widely available, e.g. the RIF-1 fibrosarcoma grown in C₃H mice.¹ Such tumor models have been extensively studied by MRS, to monitor tumor biology and physiology, and also for the development of new pulse sequences or other technical improvements. The use of MRS to study experimental tumor models,² and general work on rodent tumor models³ have been reviewed. Now that there are many clinical MR instruments, the noninvasive examination of rodent tumors by MRS is directly applicable to humans. In this article we consider the MR nuclei that have been observed in spectroscopic studies of animal tumor models.

2 ³¹P MAGNETIC RESONANCE SPECTROSCOPY

The nucleus most commonly observed in MRS studies of tumors is ³¹P which has several desirable spectroscopic properties. Phosphorus-31 is 100% abundant and is one of the more sensitive nuclei (see Table 1), and ³¹P spectra are simple and easy to interpret. Also, several important phosphorus-containing compounds occur in living systems at high enough concentrations to be detectable by ³¹P MRS (>0.2 mM), thus providing an ideal means of monitoring the energetic state of tumors.

In vivo ³¹P MR spectra of animal tumors were first reported using simple surface coils and pulse-acquire protocols.⁴⁻⁷ A typical spectrum taken from a mouse tumor is shown in Figure 1(a). Metabolites detected include three resonances from the α , β , and γ phosphates of NTP (predominantly ATP), inorganic phosphate (Pi), phosphocreatine (PCr), and both reduced and oxidized pyridine dinucleotides (NAD⁺ and NADH) which appear as a shoulder on the high field side of α -NTP. Phospholipid metabolites observed include phosphomonoesters (PME), primarily consisting of phosphocholine (PC) and phosphoethanolamine (PE), and phosphodiester (PDE), primarily consisting of glycerophos-

phocholine (GPC) and glycerophosphoethanolamine (GPE). These resonance assignments have been confirmed by ³¹P high resolution MRS analysis of PCA extracts.⁸ Intracellular tumor pH can also be derived from the chemical shift of the Pi signal.⁹

Several changes of ³¹P spectra are consistently seen during unperturbed tumor growth. These include larger Pi resonances than observed in normal tissues, high PME resonances that increase with tumor growth, decreasing PCr levels when detectable, and a size-dependent decline in NTP relative to Pi, coupled with a decrease in tumor pH. As in nutritional deprivation in tumors, NTP decreases as Pi increases and the resultant ratio of 'high energy' to 'low energy' phosphates, i.e. NTP/Pi, is often used as a measure of metabolic state.

The decline in the bioenergetic status of the tumor is consistent with the tumor vasculature becoming incapable of providing a nutritive blood (and hence oxygen) supply to the rapidly proliferating tissue, leading to the onset and development of hypoxia.^{10,11} Tumor acidification also reflects poor vascularity, as the large amounts of H⁺ ions produced by glycolysis accumulate extracellularly.¹² The large PME

Figure 1 ³¹P ISIS spectra of an RIF-1 fibrosarcoma in a C₃H mouse (a) before and (b) after i.v. injection of 5 mg kg⁻¹ hydralazine. Peak assignments are: 1, PME; 2, Pi; 3, PDE; 4, PCr; 5, γ -NTP; 6, α -NTP; 7, NAD⁺/NADH; and 8, β -NTP

Table 1

Nuclide	Sensitivity	% Natural Abundance	Chemical Shift Range (ppm)	Comments
^1H	1.00	100	10	amino acids, lactate
^{31}P	0.066	100	30	energy metabolism, pH, phospholipid metabolites
^{13}C	0.016	1.1	200	tumor metabolism
^{19}F	0.833	100	250	drug metabolism, blood flow
^2H	0.010	0.015	10	blood flow, pharmacokinetic analysis

and PDE resonances in ^{31}P spectra are related to cell membrane turnover in tumors. As both PC and PE are membrane synthesis substrates and GPC and GPE are membrane breakdown products, changes in the PME/PDE ratio may correspond to high rates of membrane synthesis within rapidly proliferating tissue or membrane decomposition within necrotic regions.¹³

Phosphorus-31 MR spectroscopy has also revealed alterations in the energy and phospholipid metabolism of tumors during response to treatment. The first use of ^{31}P MRS to monitor the response of animal tumors to radiotherapy showed an increase in intensity of the PCr resonance at 28 and 40 h post irradiation.⁶ Subsequent studies have shown a common pattern of response to radiation therapy, with an observed increase in PCr/Pi, NTP/Pi, and intracellular pH, the extent of response being dose dependent and not a systemic response to radiation toxicity.¹⁴ This observed improvement in energetic status is consistent with tumor reoxygenation, i.e. the reacquisition of radiosensitivity of cells that have survived irradiation because they were hypoxic at the time of exposure; it may result from increases in tumor blood perfusion after irradiation.¹⁵ Another possible explanation for the improvement in cell energy status is the reduced oxygen demand, which is a consequence of cessation of growth, as well as an improved blood supply as the tumor shrinks.¹⁶

The response of animal tumors to a range of chemotherapeutic agents has also been observed by ^{31}P MRS. Agents such as cyclophosphamide and 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) increase the levels of high-energy phosphates,^{16,17} the reverse of the ^{31}P trends seen during unperturbed tumor growth. This response is accompanied by a decrease in tumor volume, yet the changes in ^{31}P MR spectra are detectable early after initiation of treatment, before measurable changes in tumor size are evident.¹⁶ Other agents such as flavone acetic acid (FAA) induce metabolic deactivation of animal tumors as observed by ^{31}P MRS, i.e. decreased NTP levels. FAA causes a reduction in perfusion by causing vascular collapse, though the exact mechanism of action, as with many of these drugs, is still unclear.¹⁸

Improving or decreasing tumor blood flow, and hence tumor oxygenation, could facilitate tumor therapy. Acute manipulation of tumor blood flow by a range of noncytotoxic modifiers has been studied by ^{31}P MRS. Injection of agents such as nicotinamide or administration of 100% oxygen have led to improved

bioenergetic status as seen by ^{31}P MRS, thus potentially rendering the tumor more susceptible to radiotherapy or improving drug delivery.^{19,20} Conversely, modifiers such as hydralazine, a vasodilator acting directly on host vascular smooth muscle, decrease tumor perfusion, resulting in a decrease in NTP/Pi and pH in transplanted tumors, as depicted in Figure 1(b). These changes occur as blood is 'stolen' from the tumor, leading to vascular collapse. Such a response, however, has not been observed in spontaneous animal tumor models.²¹

The marked changes in energy metabolism seen in animal tumors are rarely observed in patients. However, the PME peak does change markedly in tumors in patients; it rises during tumor growth and decreases after successful therapy.²² Such changes have also been observed and studied in animal models.²³

3 ^2H MAGNETIC RESONANCE SPECTROSCOPY

The use of ^2H in spectroscopic studies of animal tumors has centered upon the observation of the uptake or clearance of the freely diffusible, nonradioactive tracer deuterium oxide ($^2\text{H}_2\text{O}$) to measure tumor blood flow (TBF).²⁴ Tumor blood flow is an important determinant of the response of solid tumors to treatment and can also be altered by treatment.

Two distinct approaches have been used. Initially, $^2\text{H}_2\text{O}$ clearance after a direct intratumor bolus injection was measured to give information on local TBF.²⁵ This method is easy to implement and generates numerical values in mL (100 g min^{-1}) for TBF by fitting the data to an appropriate model, but it only measures TBF in the local area of injection and the injection itself may disrupt the tumor vasculature. Alternatively, $^2\text{H}_2\text{O}$ uptake by the tumor after i.v. injection has been observed by ^2H MRS (Figure 2); this method does not directly affect the tumor tissue and reports TBF throughout the whole tumor. This latter approach is ideal for measuring relative TBF and the response to blood flow modifiers, though quantification of TBF is more complicated and requires knowledge of the arterial input function, i.e. the $^2\text{H}_2\text{O}$ concentration in the arterial blood.²⁶

Administration of $^2\text{H}_2\text{O}$ allows repeated measurements to be made on the same tumor; hence changes in TBF in response to therapy or blood flow modifiers can be easily assessed. For example, relative TBF in response to hyperthermia showed a significant difference at 45 °C compared with control tumors at

Figure 2 Uptake of $^2\text{H}_2\text{O}$ into a GH3 prolactinoma in a Wistar Furth rat as a function of time. Eight background FIDs collected prior to a bolus injection of $300\ \mu\text{l}\ ^2\text{H}_2\text{O}$

37°C .²⁶ Relative TBF was also shown to decrease in response to the vasodilator hydralazine, as observed by ^2H MRS.²⁷

Adaptation of these techniques to a ^2H imaging experiment has also been accomplished, and imaging the distribution of uptake of $^2\text{H}_2\text{O}$ provides an indication of tumor vascularity. From measurement of $^2\text{H}_2\text{O}$ accumulation into each pixel, a map of the spatial blood flow distribution can be created which is useful in assessing the characteristic heterogeneity of tumor blood flow.²⁸ Deuterium MRS provides reliable data on TBF when used with caution and provides a useful, noninvasive method of assessing an important determinant of tumor physiology.

Hydrogen-2 MRS has also been used for the direct *in vivo* measurement of drug concentrations. Using deuterated drugs such as ^2H -misonidazole, the concentration of the drug can be determined from a single ^2H NMR spectrum with a limit of detection of approximately 0.5 mM for a drug labeled with three equivalent deuterons.²⁹

4 ^{13}C MAGNETIC RESONANCE SPECTROSCOPY

Carbon-13 MRS has been little used to study cancer. This is due in part to the relatively low natural abundance and sensitivity of the ^{13}C nucleus relative to ^1H (see Table 1) which causes two problems: (i) it is necessary to use high concentrations of ^{13}C labeled substrates, which can be expensive to synthesize; and (ii) the large amount of the compound that is administered may alter tumor metabolism. In spite of these limitations, the use and application of both enrichment studies and natural abundance ^{13}C studies to monitor tumor biochemistry has progressed. Most ^{13}C studies in animals have used labeled substrates injected directly into a tumor to increase the signal-to-noise ratio. Also, more efficient probe designs have been developed to overcome the limitations associated with ^{13}C MRS.³⁰

The major application of *in vivo* ^{13}C MRS for studying cancer is to monitor glycolysis and the rate of energy utilization of tumors relative to normal tissue. Compounds such as glucose, citrate, and alanine can be detected. The presence (or absence) of several compounds can be detected, along with their concentration, mobility, and relaxation characteristics, simultaneously and noninvasively in one animal.

In vivo ^{13}C studies are routinely performed to obtain a background spectrum before injection of labeled substrates (see below). Typical studies take several minutes using ^1H decou-

pling (which increases the ^{13}C spectral resolution by removing the coupling interactions with neighboring protons whilst allowing NOE) to obtain spectra with adequate signal-to-noise ratios. For example, natural abundance ^{13}C MRS of Dunning rat tumors, a model for human prostate cancer, was used to examine the relationship between prostatic tumors and the presence or absence of citrate.³¹

Recently, ^{13}C MRS has been used in combination with ^{31}P MRS and traditional biochemical methods to examine glucose metabolism in RIF-1 tumors.^{32,33} Natural abundance ^{13}C spectra were acquired from tumors to obtain a background signal from endogenous lipids ($-\text{CH}_2-$) which was used as an internal chemical shift marker; the mice were then injected intratumorally with ^{13}C labeled glucose and proton-decoupled ^{13}C spectra were acquired for 70 min. The levels of 3- ^{13}C lactate and 3- ^{13}C alanine were increased and the level of lactate approached a steady state at approximately 40 min after injection.

Carbon-13 MRS has also been used after intraperitoneal and intravenous administration of glucose to study tumor metabolism (Figure 3) and to monitor the generation of lactic acid. In addition to the study of subcutaneous (s.c.) tumors, brain tumor metabolism has also been examined with ^{13}C MRS.³⁴

So far, ^{13}C MRS has been used to study the relationship between glucose availability and tumor metabolism. Although these natural abundance and enrichment studies demonstrate the feasibility of oncological applications of *in vivo* ^{13}C MRS, to date, there have been no reported studies in which it has been used to monitor tumor metabolism after therapy.

Another application of ^{13}C MRS is to follow the pharmacokinetics of ^{13}C -labeled chemotherapeutic agents. This labeling is attractive as most drugs contain carbon and usually there is one position that can be labeled during drug synthesis, thus removing the need for a label that might modify drug activity (e.g. ^{19}F). However, detection of the drug *in vivo* presents a challenge because of the poor sensitivity. One study has demonstrated the detection of a ^{13}C label on the active methyl group of the methylating agent temozolamide in RIF-1 fibrosarcomas with sufficient sensitivity to determine a half-life for elimination from the tumor.³⁵

5 ^{19}F MAGNETIC RESONANCE SPECTROSCOPY

The ^{19}F nucleus is an excellent nuclide to monitor by MRS because it is 100% naturally occurring and has a sensitivity nearly equal to that of ^1H (see Table 1) and there is no background signal *in vivo*. The noninvasive nature of ^{19}F MRS also makes it a useful tool for monitoring *in vivo* drug metabolism since it is not necessary to sacrifice a large number of animals and each animal can serve as its own control.

Fluorine-19 MRS has been extensively used in oncology. Most of the work has used fluorine-substituted chemotherapeutic drugs such as the fluoropyrimidines. There has also been work done using perfluorocarbons (hydrocarbons whose protons have been replaced with fluorine nuclei), which are ideal candidates for both spectroscopy and imaging. Other applications of ^{19}F MRS in cancer research in murine tumors include the use of compounds containing ^{19}F as probes for tumor hypoxia,^{36,37} intracellular pH,³⁸ and for monitoring tumor therapy.³⁹

Figure 3 $^{13}\text{C}\{^1\text{H}\}$ MR spectrum of an RIF-1 tumor in a C_3H mouse after i.v. injection of 7 mg kg^{-1} $1\text{-}^{13}\text{C}$ -glucose. Peak assignments are: 1, carbonyl carbons ($\text{C}=\text{O}$); 2, alkene carbons ($\text{C}=\text{C}$); 3, β -glucose; 4, α -glucose; 5, methylene carbons (CH_2), and 6, lactate. Figure supplied by Dr R. J. Maxwell

The fluoropyrimidine that has been most widely studied by ^{19}F MRS is 5-fluorouracil (5-FU), an effective anticancer agent that has been used clinically since 1957.⁴⁰ 5-FU was synthesized as an antimetabolite of uracil and is almost always metabolized similarly to uracil and its breakdown products (Figure 4). It is commonly used in combination chemotherapy with agents such as methotrexate or adriamycin.⁴¹ The first reported study monitored 5-FU metabolism in the livers and tumors of mice via ^{19}F MRS.⁴² A more recent review explores the potential of ^{19}F MRS of fluoropyrimidines for monitoring the therapy of single chemotherapeutic agents or combinations.⁴³ There have also been studies using ^{19}F MRS to monitor 5-FU therapy in patients.⁴⁴

Recently, ^{19}F MRS of perfluorocarbon emulsions has been used to examine changes in the oxygenation status of mouse RIF-1 tumors in response to treatment with nicotinamide.⁴⁵ Consistent with the hypothesis that nicotinamide improves tumor oxygenation (see above), there was a significant increase in $p\text{O}_2$ for treated tumors versus control tumors. The perfluorocarbon emulsions have several features that make them ideal candidates for ^{19}F MRS measurements of tumor oxygenation status: (i) they are selectively sequestered in solid tumors; (ii)

oxygen binding changes the spin-lattice (T_1) relaxation time of the fluorocarbon; and (iii) there is a linear correlation between the T_1 value of the perfluorocarbon in the tumor and the tumor oxygenation.^{45,46}

^{19}F MRS can also be used to observe the behavior of organofluorides such as halothane in vivo. The inhalant anaesthetic, halothane, is a hydrophobic probe that can be used for monitoring plasma membrane alterations and thus may have potential for determining the effectiveness of treatments such as hyperthermia.⁴⁷

6 ^1H MAGNETIC RESONANCE SPECTROSCOPY

Studies of animal tumors by ^1H MRS are few, even though protons are naturally occurring and ^1H is the most sensitive nucleus (Table 1). Although ^1H MRS allows observation of several metabolites that are not detected by MRS of other nuclei, and nearly every compound in living tissues contains hydrogen atoms, there are several disadvantages associated with its application in vivo. The major obstacles are the high concentrations of tissue water (ca. 40 M) and lipids (ca. 1 mM)

Figure 4 ^{19}F spectrum showing uptake of 5-FU into a GH3 prolactinoma in a Wistar Furth rat after i.v. injection of 60 mg kg^{-1} 5-FU. Peak assignments are: 1, fluoronucleotides; 2, 5-fluorouracil; and 3, fluoro- β -alanine. Figure supplied by Dr R. J. Maxwell

which produce intense background signals that must be suppressed to observe the metabolites of interest. The small chemical shift range of ^1H signals means the B_0 field must be shimmed precisely. Local hemorrhaging within the tumor, or motion, can degrade spectral resolution.⁴⁸ Because of these problems, most of the studies to date have been limited to intracranial (brain) tumor models which have very little motion and less intense lipid signals.^{49,50}

The resonances that appear in a water-suppressed ^1H spectrum differ, depending on the echo time that is used. Typical resonances observed at 'long' echo times (e.g. 240–270 ms) may include total creatines, total cholines, and lactate. Resonances attributed to inositol, glucose, and mobile lipids may appear at 'short' echo times (e.g. 20–50 ms).

Recently, water- and lipid-suppressed ^1H spectra of subcutaneous RIF-1 and EMT-6 tumors have been published.⁵¹ There were no changes in metabolite levels during untreated tumor growth, and tumor response to treatment with 5-FU resulted in a decrease in all metabolites. Acute TBF reduction by hydralazine (see above) caused a twofold increase in lactate. Also, ^1H spectroscopic images of RIF-1 tumors showed that radiotherapy significantly decreased lactate levels.^{52,53} These experiments demonstrate the feasibility of ^1H MRS outside the brain.

Preliminary ^1H MRS studies in animal tumors demonstrate the wealth of information that can be exploited once the technical obstacles have been overcome. Such approaches may therefore be extrapolated into the clinical arena.

7 SUMMARY

Animal tumor models have already been extensively studied by MRS: a recent review cites more than 100 papers on ^{31}P MRS alone.²³ The ability to monitor endogenous intracellular metabolism, drug metabolism, tumor blood flow, or tumor intracellular pH repeatedly and noninvasively in a single animal, and to combine various monitoring procedures in a single experiment, has provided a great advance in experimental oncology.

Médecine, Marseille, France*

1 INTRODUCTION

Biochemistry has been based for a long time on the identification of molecules involved in the complex architecture and organization of living systems. Prerequisites to the identification of these molecules are their extraction from cells, their chemical and structural analysis, and their quantitation. High-resolution magnetic resonance spectroscopy (MRS) of tissue and cell extracts has been playing a growing role over the past 15 years in the identification of key molecules participating in biochemical processes (metabolism). In the 1990s, studies by MRS of extracts have generated more than 100 publications per year and are often considered as a required complement to *in vivo* and *ex vivo* experiments.

MRS of extracts is gradually developing into a major analytical technique. It combines the most advanced magnetic resonance technology (spectrometers) and methods (pulse sequences) with the methods of biochemical extraction and separation based on chemical and physicochemical properties of molecules. In most cases, the MR spectrometer analyses complex mixtures of compounds in a way which is similar to the detector of a gas chromatograph or the chamber of a mass spectrometer. In some cases, chromatographic separation and subsequent analysis of compounds by MRS have been combined online in the same apparatus as in the coupling of a MR spectrometer with a high-performance liquid chromatograph.

There are many compelling reasons for an MR spectroscopist to analyze tissue and cell extracts. The first pertains to the assignments of resonances in spectra recorded *ex vivo* and *in vivo* on organs, animals, and humans, accounting for about 20% of publications on the subject. The second reason of interest is the description and monitoring of normal and pathological metabolism in cells and organs (respectively 34% and 21% of publications), essentially using isotope labeling. Attempts at diagnosing pathologies based on the analysis of human tissue extracts are being made (6% of publications). Finally, the field of pharmacology (bioconversion of drugs, pharmacokinetics, effect of drugs on metabolism) benefits significantly from the MRS analysis of extracts (19% of publications).

In this chapter, we are not aiming to cover exhaustively the field of MRS of extracts. Instead of presenting a comprehensive review, we will try to illustrate what is unique to MRS of tissue and cell extracts in the general context of analytical techniques and modern studies of metabolism.

2 TECHNICAL ASPECTS

The extraction of compounds to be analyzed by MRS has to meet two requirements. It must be *selective* in order to separate molecules of interest from unwanted compounds or cellular substructures (cell debris, membranes etc.). Also, the extraction procedure has to *avoid/limit the degradation and chemical transformation* of molecules. Treatment by perchloric acid is a widely used general method of extraction of water-soluble metabolites.¹ This method requires neutralization and allows removal of salts and proteins by centrifugation (pellet). Perchloric extraction usually follows freeze-clamping of tissues to stop metabolism. It is routinely conducted at a temperature below 5 °C in order to avoid/limit enzymatic or chemical degradation of extracted metabolites. In some cases, inhibitors of enzymatic activity can be added in the supernatant. Other methods are more specific of particular metabolites. For example, extraction by NaOH is used to obtain glycogen and extraction of lipids requires an organic phase such as a 2:1 mixture of chloroform and methanol.²

Extracts have to be stored at very low temperature (deep freezer at –80 °C or liquid nitrogen) to limit degradation. Progressive thawing is also critical since chemical modifications of metabolites may occur during this process.

It should be kept in mind that extraction procedures may give a distorted image of the biological reality. Aggressive procedures such as extraction by strong acids or organic solvents modify very significantly the physicochemical environment of metabolites, as compared with the one they experience in the intact cell. As an example, the ionic environment is modified at very low pH (perchloric acid) or when protons and water molecules are lost in organic phases.

Finally, all metabolites are not equal with respect to extraction procedures. They display wide variations in chemical stability, binding properties, conformational rearrangement etc. Hence, one should exert caution when comparing metabolic profiles obtained by *in vivo* MRS with results obtained on extracts by *in vitro* MRS. The comparison can be at best misleading if appropriate control experiments are not run since the information offered by extracts is, in essence, different from the information obtained by localized *in vivo* MR spectroscopy.

MRS of extracts does not require customized MR spectrometers. Standard high-field spectrometers (4.7–18 T) can be used with either narrow-bore or wide-bore magnets. No specific developments in the hardware or software are necessary and MRS of extracts can be performed at any MR laboratory with a basic knowledge of NMR techniques.

3 TISSUE EXTRACTS FOR RESONANCE ASSIGNMENTS

Specific assignment of the resonances recorded *in vivo* on an MR spectrum remains a critical issue, and a growing one, in consideration of the multiplicity of new applications of MRS in metabolic, pharmacological, and medical studies. Assignment is undoubtedly facilitated by the analysis of extracts using data banks (chemical shifts, coupling patterns, coupling constants), pH titration, and selective addition of authentic compounds to extracts.³ Also, one can use the whole arsenal of pulse sequences and multinuclear approaches that the chemists have

Figure 1 Proton MR spectrum (400 MHz) of a perchloric extract of rat gastrocnemius muscle obtained after freeze-clamping. The supernatant is lyophilized in order to eliminate water. Then the metabolites are dissolved in D₂O. Main Figure: aliphatic region of the spectrum (0–5 ppm). Inset: aromatic region of the spectrum (5–12 ppm). Abbreviations: PC, phosphorylcholine; GPC, glycerophosphorylcholine; PCr, phosphocreatine; ASP, aspartate; GLN, glutamine; GLU, glutamate; NAD, nicotinamide-adenine dinucleotide; AMP, adenosine monophosphate; IMP, inosine monophosphate; HIS, histidine; PHE, phenylalanine; TYR, tyrosine; CTP, cytidine 5'-triphosphate; GTP, guanosine 5'-triphosphate; ATP, adenosine triphosphate

developed in high-resolution MRS of organic compounds.^{4–6} With the limitation already mentioned, *in vitro* MRS of extracts provides the best basis for the assignments of *in vivo* and *ex vivo* spectra. (See Figure 1.)

Extracts reflect a 'frozen situation' in cell metabolism which is often an advantage. Spectral resolution is always superior *in vitro* vs. *in vivo* and *ex vivo* by several orders of magnitude and facilitates the interpretation of spectra recorded on living cells, tissues, and organs. Interestingly, assignments of resonances in extracts have revealed the presence of unexpected compounds in plants, yeasts, bacteria, and human tissues,^{7,8} the identification of which has required chromatographic separation and chemical structure identification by standard analytical techniques, including high-resolution MRS. In these instances, MRS of extracts has directly contributed to a better understanding of metabolic events occurring in the cell.

4 TISSUE EXTRACTS IN METABOLIC STUDIES

MRS of tissue extracts has played a major role in the study of metabolism of cells and organs. Two strategies have been

used. The first strategy is 'passive' and consists of the detection and dosage of the metabolites present in the tissue extract reflecting, as a snapshot, the metabolic status of the living tissue at the time of extraction. Quantitation can be achieved with respect to wet weight of tissue, protein content, or an internal reference (e.g., an endogenous compound of known concentration). Proton and ¹³C MR spectra bear information on the intermediary metabolism (amino acids, lipids, Krebs cycle intermediates, etc.). Phosphorus-31 MR spectra carry different information depending on the type of extraction. Aqueous extracts contain phosphorylated molecules of energy metabolism (ATP, creatine phosphate, phosphomonoesters and phosphodiester, inorganic phosphate, etc.). (See Figure 2.) The polar head groups of many phospholipids can be assayed on lipidic extracts. In fact, ³¹P MRS provides a viable alternative to the quantitative assay of phospholipids. (See Figure 3.)

The second strategy is 'active' and involves the perfusion of a selectively ¹³C-enriched substrate prior to the freeze of metabolic activity and subsequent extraction. By choosing appropriately both the enriched molecule and the chemical site of the enrichment on the molecule, specific metabolic pathways can be singled out and monitored and metabolic fluxes can be

Figure 2 Phosphorus-31 MR (162 MHz) spectrum of a perchloric extract of RINm5F cells cultured in Dulbecco's Modified Eagle's Medium containing glucose. This spectrum (sum of 4800 scans, with complete proton decoupling) corresponds to the perchloric extract of 6×10^8 RINm5F cells cultured in flasks. Abbreviations: PC, phosphorylcholine; SP, sugar phosphate; PCr, phosphocreatine; DPDE, diphosphodiester; NTP, nucleoside triphosphates; NDP, nucleoside diphosphates

quantitated under a variety of conditions, in relation to pathological state, cell differentiation,⁹ cell growth, aging etc. This approach is widely used on perfused organs and cultured cells. In these experiments, extracts are prepared and analyzed at specific times to follow up the conversion and biodistribution of the ^{13}C marker. Basic metabolic events have been documented such as the phosphorylation status of liver under normal conditions¹⁰ or in the presence of ethanol, the metabolism of acetate,¹¹ or the redox state of the brain,^{12,13} etc.

Cellular compartmentation can also be studied from a metabolic standpoint and particularly interesting information has been obtained in brain tissue to shed additional light on the respective role of glial and neuronal cells.¹⁴

Particular attention has been devoted to the study of metabolic disorders in relation to cancer. The reader is referred to the abundant literature on this subject^{15,16} which illustrates the large extent to which MRS of extracts has become an indispensable analytical tool to study normal and pathological metabolism in cells and tissues.

5 APPLICATIONS TO PHARMACOLOGY

Besides the study of cell metabolism, and naturally occurring metabolites, MRS of extracts can document the metabolic fate and the metabolic impact of xenobiotics. Bioconversion of drugs can be readily studied with unsurpassed accuracy. The same MRS analysis can detect, identify (structure), and quantitate the metabolites to which a drug is converted and the kinetics of their appearance.¹⁷

Prototype studies have been conducted on antimitotic, antifungal, and antiviral drugs.^{18,19} The analysis of drug metabolites benefits from the use of selective isotope labeling and multinuclear (^{31}P , ^{19}F , ^{13}C , ^2H) and multidimensional MRS experiments.

A second pharmacological application of MRS of extracts is the evaluation of the metabolic changes induced by the administration of a drug. As an example, the impact of the different interleukins on cell metabolism is not well known. However, obtaining additional information is critical to develop, adapt, and optimize anticancer treatment using this new family of molecules. MRS plays a key role in evaluating the effect of these peptides on the general metabolism of the patient toward eliciting the adequate immune response to the presence of a cancer.²⁰ Drug resistance, another new problem of public health, is currently tackled by MRS of extracts in bacterial and eukaryotic cells, animal models, and even patients in an attempt to establish some metabolic basis to the alarming decrease in therapeutic efficacy of a number of antibiotic and antimitotic drugs.^{21,22}

6 NEW DIRECTIONS: TOWARD MEDICAL DIAGNOSIS BY MRS OF TISSUE EXTRACTS

Tissue characterization in medicine is essentially based on the methods developed in pathology and cytology with a large role devoted to optical and electronic microscopy, and the use of selective dyes and immunological labeling. Biochemical studies of excised tissues is not common at the hospital, with the exception of blood and some body fluids. The analysis of tissue biopsies is a growing area of application for the MRS of extracts. Muscle and brain biopsies have been studied but most of the work done to date has focused on human tissues biopsies: breast cancer,²³ uterus,²⁴ colon.²⁵ As a matter of fact, the knowledge of the metabolic features of a cancer tumor is of the utmost interest in diagnosis, prognosis and therapeutic decisions.²⁶ Specific metabolic profiles are observed from extracts of malignant tumors with deviations in the metabolism of amino acids and lipids/phospholipids.^{24,27} (See Figure 3.)

Figure 3 Phosphorus-31 MR (162 MHz) spectrum of a control plasma lipid extract. A line broadening of 4 Hz was applied. Abbreviations: SM, sphingomyelin; PC, phosphatidylcholine; LPC, lysophosphatidylcholine; TP, triethyl phosphate

The wealth of information that is available on the spectra (usually proton spectra) of biopsy extracts has prompted new strategies for data processing and analysis, based on pattern recognition, neural networks, and chemometrics.^{28,29} This integrated and automated approach to spectral processing should facilitate very significantly the acceptance of MRS of biopsy extracts in routine medical diagnosis.

7 CONCLUSIONS

Obviously, MRS of extracts is not 'the MRS of the poor' that scientists and clinicians use when they do not have access to sophisticated methods of in vivo spectroscopy. It is making a definite contribution to the understanding of normal and pathological cell metabolism when it is submitted to a variety of perturbations. MRS of extracts is a cost-effective, highly informational, easy-to-use analytical procedure which is now entering the field of clinical biology by providing unique information that the medical profession can readily use for diagnosis, treatment, and prognosis. (See Figure 4.)

Tissue NMR Ex Vivo

Ian C. P. Smith and Tedros Bezabeh

National Research Council of Canada, Winnipeg, Canada

1 INTRODUCTION

NMR of tissue specimens is now an established, powerful adjunct to histopathology for classification of human cancers. The present article is an update of earlier reports.^{1,2} The initial study that provided insight into the potential of NMR for the early detection and diagnosis of cancer was reported in 1980 for mouse thymus.³ Spectral changes preceded the cellular changes observed by histopathology, suggesting that the tissue NMR method could detect preinvasive changes prior to any morphological manifestation. This was supported by a study of a rat mammary model for adenocarcinoma metastasis.⁴ Spectra from the excised tumor closely resembled those from suspensions of the same cells grown in vitro. The T_2 relaxation time for the strong peak at 1.3 ppm correlated well with the metastatic potential of this tumor in the rat.

This early success with a rat model led to similar studies with human tissues. Human colorectal tumors yielded spectra with some parameters similar to those obtained from rat mammary adenocarcinoma. Over 90% of the human colorectal tumors gave long T_2 relaxation values for the resonance at 1.3 ppm, implying a high metastatic potential.⁵ Patient follow-up showed no false positives; that is, no patients whose tumor generated only a short T_2 relaxation value for the resonance at 1.3 ppm developed secondary tumors.⁶ Many of those with long T_2 relaxation values did develop secondary tumors.

From these studies it was apparent that the strong signals from fat were superimposed upon those of potentially diagnostic species present in the spectra from colorectal biopsies, a problem now known to exist also for lymph node and breast tissues. The implementation of two-dimensional (2D) NMR spectroscopy was a valuable complement, especially when 1D spectra were complex.⁷

Tissue NMR ex vivo has so far been primarily performed on ^1H nuclei. This is mainly because of the high sensitivity of ^1H NMR spectroscopy and the stability of the proton-containing compounds/metabolites in an excised tissue that are of diagnostic interest. Natural abundance ^{13}C NMR spectroscopy would take unreasonably long acquisition time and, therefore, is not ideal for a study of an excised/isolated piece of tissue. The instability (hydrolysis) of the high-energy phosphates [e.g., phosphocreatine (PCr), ATP] after the removal of the tissue from the system makes the use of ^{31}P NMR spectroscopy impractical.

Tissue NMR ex vivo offers an advantage over NMR of cell cultures and extracts in that it provides a situation similar to that in vivo. In particular, it helps in the examination of the biological properties of tissue that are dependent on architecture and morphology, which is impossible to do with extracts and isolated cells. Another advantage of tissue NMR ex vivo is

its nondestructive character; the tissue can be submitted for histopathological assessment following the NMR experiment, enabling a direct correlation between the histopathological and MR spectral features of the same tissue specimen. As a result, no additional biopsy need be taken for the study since the clinical diagnosis can be made on the MRS sample, with no compromises or artifacts.

2 METHODS

All successful studies of viable tissues have relied heavily on careful sample handling prior to ^1H MRS experiments.⁸ Tissues are placed into sterile tubes immediately after excision, immersed in liquid nitrogen, and stored at -70°C . Either a glass wool platform supports the sample surrounded by buffer,⁷ or the specimen is inserted into a capillary containing buffer,⁸ which in turn is inserted into an NMR tube containing the same buffer and a reference. This latter method of sample positioning has several advantages including measurable volume for quantification and easier homogeneity adjustment (Figure 1).

Time constraints imposed by the limited viability of cell and tissue specimens dictate careful selection of acquisition parameters for 2D NMR spectroscopy. In order to obtain a pathological assessment of the sample used for NMR, time in the instrument must be minimized. Therefore, the trade-off between signal strength, spectral resolution, and sample viability must be addressed for each tissue type. Cells and tissues contain a variety of biochemical species at a range of concentrations, with T_2 relaxation times ranging from <100 ms to >1 s and, therefore, care must be taken with signal processing. It is imperative that histological examination be undertaken on the NMR specimen itself, rather than relying upon the routine

Figure 1 Schematic of the positioning of a small tissue specimen in a capillary tube. (Reproduced with permission from Kuesel et al., *Magn. Reson. Med.*, 1992, 27, 349–355. Copyright © 1992, Wiley-Liss)

hospital report. Spectral analysis is best made by nonsubjective multivariate methods (see below).

We describe below studies on tissue from a variety of organs, each representing a solution to different technical/clinical problems: (1) the distinction between preinvasive and invasive cancers; (2) the presence of significant levels of fat, obscuring signals of interest; and (3) the detection of cellular abnormalities which are not morphologically manifest.

3 CERVIX

Cervical epithelium has preinvasive states that are well documented by histopathology. Independent clinical studies in two laboratories have shown that ^1H NMR can distinguish between preinvasive lesions, including carcinoma in situ (CIS), and frankly invasive cervical cancer with $p < 0.0001$ (Student t -test).⁷⁻⁹ The ^1H NMR acquisitions are completed in 15 min, and the tissue is not subject to the vagaries of sampling since the entire punch biopsy specimen is examined. Two different approaches have been used for spectral analysis. In one, manual measurements of peak heights were performed. Typical spectra of preinvasive and invasive cervical epithelium are characterized by intense lipid resonances at 0.9, 1.3, and 5.2 ppm. In contrast, spectra of preinvasive lesions are free of signals from high-resolution lipid.⁹ A second spectral region which provides diagnostic information lies between 3.4 and 4.2 ppm. The ratio of the strongest resonance between 3.4 and 4.2 ppm and the methylene resonance at 1.3 ppm, is plotted against the ratio of the methylene to methyl resonances at 1.3 and 0.9 ppm, respectively (Figure 2). The separation between the mean ratio values for CIN3 and invasive cancer is significant. The p values obtained when comparing invasive cancer to the low, moderate, or severe levels of dysplasia are all <0.0001 , with a specificity of 0.94 and sensitivity of 0.98.⁹

Alternatively, a mathematical treatment of the data sets may be used. A variety of multivariate analyses, such as linear discriminant analysis, neural nets, and genetic programming were applied to these data. Using a consensus approach for a series of 150 spectra of cervical tissue, spectra were allocated to characteristic groups. Groupings were then compared with the data from histopathology,¹⁰ and yielded sensitivities and specificities greater than 0.99 for the various levels of dysplasia. In a recent study of 196 cervical punch biopsies (nondysplastic and dysplastic of varying grades), it was found that classification of the spectra into four diagnostic groups (i.e., nondysplastic, CIN1, CIN2, and CIN3) was difficult.¹¹ This could be because the inter-class biochemical changes that help to differentiate between these groups are very small compared with the sensitivity of NMR spectroscopy. However, multivariate classification of the spectra into two groups, i.e., nondysplastic and CIN1 versus CIN2 and CIN3, yielded a much better classification accuracy.

Chemical shift imaging (CSI) has the potential to revolutionize the detection of cancers since it can provide information on the biochemical composition and distribution, and the spatial location, of neoplasms. In CSI the image is constituted from a single specific frequency. Water-based CSI images (excitation at 4.8 ppm) of cervical punch biopsies from invasive adenocarcinoma and low-grade squamous dysplasia show

Figure 2 Peak height ratios from one-dimensional ^1H NMR spectra.¹² Severely dysplastic epithelium (CIN3) is compared with invasive carcinoma. The cross bars show the mean $\pm$ standard deviation. (Reproduced with permission from Delikatny et al., Proton NMR and human cervical neoplasia: ex vivo spectroscopy allows distinction of invasive carcinoma of the cervix from carcinoma in situ and other preinvasive lesions. *Radiology*, 1993, **188**, 791-796)

that both biopsies appear with equal intensity. However, when a lipid-based CSI (excitation at 1.3 ppm) is performed on the biopsies, only the malignant specimen shows a substantial accumulation of MR-visible lipids.¹²

4 THYROID

The thyroid is the first organ where NMR has distinguished between benign adenoma and carcinoma which are morphologically identical under the light microscope.¹³ Histological diagnosis of follicular thyroid cancer relies upon visualization of capsular invasion or the patients having demonstrated secondary tumors. Therefore, the morphological similarity of malignant and benign follicular cells leads to surgery solely for diagnostic purposes. One-dimensional ^1H NMR spectroscopy clearly distinguishes normal thyroid tissue from morphologically distinct invasive papillary carcinoma, based on differences in the relative intensities of resonances at 1.7 and 0.9 ppm,¹⁴ demonstrating the potential to distinguish genuinely benign follicular adenomas from follicular carcinomas. The MR parameters separated follicular neoplasms into two categories, each of which was directly comparable with either normal thyroid or papillary carcinoma. The patients with clinically proven or histologically invasive follicular carcinoma were categorized by ^1H MR together with papillary cancers, as were a number of patients with clinically or morphological atypical neoplasms. It was subsequently established that the same diagnostic information could be obtained from fine needle aspiration biopsies, without recourse to surgery.¹⁵ Multivariate analysis undertaken in a blind study delineated five out of six patients with follicular carcinoma (identified clinically by the

presence of secondary tumors).¹³ A clinical trial is underway in Australia where patients with normal NMR profiles from fine needle aspiration biopsies are given the option not to undergo surgery for diagnostic purposes.

Although the 1.7/0.9 ppm intensity ratio can distinguish thyroid cancer from normal tissue with a high sensitivity,¹⁶ its specificity is relatively low. The probability of correctly identifying patients without cancer was significantly raised by using the 2.05/0.9 intensity ratio.¹⁷ Furthermore, 2D NMR spectroscopy yielded an increased incidence of cross-peaks from cholesterol/cholesteryl esters and di-/triglycerides and a decreased incidence of two unassigned cross-peaks, unique to the thyroid, for cancer specimens.¹⁷ The best accuracy was obtained via a computed consensus diagnosis (see section 9.5 below). Analysis of 107 thyroid biopsies resulted in 100% sensitivity and specificity in the training set, and 100% specificity and 98% sensitivity on samples of known malignancy in the test set.¹³

5 COLON

Colon tissue presents the technical difficulty of naturally high levels of fat,⁶ necessitating 2D NMR spectroscopy,⁶ or T_2 relaxation filters¹⁸ or very careful sample preparation¹⁹ to define the diagnostic resonances. The 2D ^1H - ^1H COSY spectra of colon-invasive adenocarcinoma indicate such diagnostic parameters as choline, choline-based metabolites, and altered lipid profiles (Figure 3). Tissues histopathologically classified as normal, while remaining distinct from the malignant spectral profile, were found to fit into two categories, one of which had some of the spectral characteristics of malignancy.¹⁸ These results suggest that ^1H MRS identifies colorectal mucosa with abnormality that is not morphologically manifest.

The NMR studies of colorectal cancer biopsies have relied heavily on the correlation of biological and genetic information with the NMR data from cultured cell lines.²⁰ It was shown that 2D NMR data for cell surface fucosyl residues identified the various preinvasive states as well as a feature unique to the carcinoma in situ.²¹ These pathological states, identifiable by NMR, include the distinction between malignant tumors and normal tissue; carcinoma in situ and frankly invasive adenocarcinoma; and the extents of dysplasia in preinvasive polyps.
